### <sup>29</sup>**Abstract**

<sup>30</sup>**Introduction:** Malaria-endemic countries are increasingly adopting data-driven risk 31 stratification, often at district or higher regional levels, to guide their intervention 32 strategies. The data typically comes from population-level surveys collected by rapid 33 diagnostic tests (RDTs), which unfortunately perform poorly in low transmission <sup>34</sup>settings. Here, we conducted a high-resolution survey of *Plasmodium falciparum* 35 prevalence rate (PfPR) in two Tanzanian districts and compared the fine-scale strata 36 obtained using data from RDTs, microscopy and quantitative polymerase chain reaction <sup>37</sup>(qPCR) assays**.** <sup>38</sup>**Methods:** A cross-sectional survey was conducted in 35 villages in Ulanga and

<sup>39</sup>Kilombero districts, south-eastern Tanzania between 2022 and 2023. We screened <sup>40</sup>7,628 individuals using RDTs (SD-BIOLINE) and microscopy, with two thirds of the 41 samples further analyzed by qPCR. The data was used to categorize each district and <sup>42</sup>village as having very low (PfPR<1%), low (1%≤PfPR<5%), moderate (5%≤PfPR<30%), 43 or high (PfPR≥30%) parasite prevalence. A generalized linear model was used to 44 analyse infection risk factors. Other metrics, including positive predictive value (PPV), <sup>45</sup>sensitivity, specificity, parasite densities, and Kappa statistics were computed for RDTs 46 or microscopy using qPCR as reference.

<sup>47</sup>**Results:** Significant fine-scale variations in malaria risk were observed within and <sup>48</sup>between districts, with village prevalence ranging from 0% to >50%. Prevalence varied <sup>49</sup>by testing method: Kilombero was low risk by RDTs (PfPR=3%) and microscopy <sup>50</sup>(PfPR=2%) but moderate by qPCR (PfPR=9%); Ulanga was high risk by RDTs <sup>51</sup>(PfPR=39%) and qPCR (PfPR=54%) but moderate by microscopy (PfPR=26%). RDTs 52 and microscopy classified majority of the 35 villages as very low to low risk (18 - 21 53 villages). In contrast, qPCR classified most villages as moderate to high risk (29 54 villages). Using qPCR as the reference, PPV for RDTs and microscopy ranged from <sup>55</sup><20% in very low transmission villages to >80% in moderate to high transmission 56 villages. Sensitivity was 62% for RDTs and 41% for microscopy; specificity was 93% 57 and 96%, respectively. Kappa values were 0.58 for RDTs and 0.42 for microscopy. 58 School-age children (5-15years) had higher malaria prevalence and parasite densities

- 59 than adults (P<0.001). High-prevalence villages also had higher parasite densities
- 60 (Spearman r=0.77, P<0.001 for qPCR;  $r=0.55$ , P=0.003 for microscopy).

<sup>61</sup>**Conclusion:** This study highlights significant fine-scale variability in malaria risk within 62 and between districts and emphasizes the variable performance of the testing methods 63 when stratifying risk. While RDTs and microscopy were effective in high-transmission 64 areas, they performed poorly in low-transmission settings; and classified most villages 65 as very low or low risk. In contrast, qPCR classified most villages as moderate or high <sup>66</sup>risk. While we cannot conclude on which public health decisions would be subject to 67 change because of these differences, the findings suggest the need for improved 68 testing approaches that are operationally feasible and sufficiently sensitive, to enable 69 precise mapping and effective targeting of malaria in such local contexts. Moreover, 70 public health authorities should recognize the strengths and limitations of their available 71 data when planning local stratification or making decisions.

<sup>72</sup>**Key words:** Malaria; Fine scale stratifications; Prevalence rate, Rapid diagnostic tests

- 73 (RDTs), Polymerase chain reaction (PCR); Microscopy; Population surveys; Micro-
- 74 stratification; Malaria screening.

### <sup>76</sup>**Background**

<sup>77</sup>Precise mapping of malaria prevalence is crucial for the eventual elimination of the 78 disease from different localities. In line with World Health Organization (WHO) 79 guidelines, National Malaria Control Programs (NMCPs) in Africa are increasingly 80 adopting data-driven stratification of malaria risk, in most cases at either district or 81 higher regional levels [1–3]. These stratifications involve assessing risk levels in<br>82 deographical areas at the subnational level (e.g. zones, regions, and districts) [2 <sup>82</sup>geographical areas at the subnational level (e.g. zones, regions, and districts) [2,4,5], 83 and can include fine scale mapping (down to wards and villages levels) as countries 84 progress towards elimination  $[6–8]$ . The data for such stratification may come from 85 health facilities, active malaria screening during population surveys, or proxy data 86 sources such as antenatal care clinic visits [6,9,10]. <sup>87</sup>When developing country-level malaria strategies, the prevalence of malaria, <sup>88</sup>representing the proportion of confirmed positive cases of *Plasmodium falciparum* (or 89 other *Plasmodium* sp.) among all individuals tested [11,12], can be classified into <sup>90</sup>various transmission categories. The WHO has previously used the following cutoff 91 points for malaria endemicities: below 1% as very low, 1-10% as low, 10-35% as 92 moderate, and above 35% as high risk malaria stratum [12]. Different NMCPs may <sup>93</sup>adapt these criteria with slight adjustments based on local epidemiological insights. For <sup>94</sup>instance, some countries, including Tanzania and Kenya, have used the parasite 95 prevalence data to categorize their geographic zones as either very low risk (PfPR < 96 1%), low risk (1%  $\leq$  PfPR  $<$  5%), moderate risk (5%  $\leq$  PfPR  $<$  30%), or high risk strata 97 (PfPR  $\geq$  30%) [2,13]. Another measure that can be used for generating these strata is <sup>98</sup>the annual parasite incidence (API), which is the number of diagnostically confirmed <sup>99</sup>malaria cases per 1000 individuals per year and is usually obtained from health facilities 100 data [12,14]. API offers precise malaria stratifications, though it fails to account for sub-<sup>101</sup>clinical malaria infections, which can contribute to transmission and impede malaria 102 elimination efforts [15].

103 National malaria programs usually rely on different actively and passively collected data 104 to inform malaria burden and monitor the effectiveness of control measures [16–18]. For 105 instance, Tanzania employs multiple platforms, including the District Health Information

106 software (DHIS2) populated with data from routine health facility visits, the Malaria

- 107 Indicator Surveys (MIS) and Tanzania Demographic and Health Surveys (TDHS), which
- 108 are done every 4-5 years through household surveys, and the school malaria parasite
- 109 surveillance targeting kids aged 5-16 years during (SMPS) [2,19–21]. A common
- 110 feature of these established systems is that most rely primarily on rapid diagnostic tests
- <sup>111</sup>(RDTs) and microscopy [13,22,23], though samples are sometime also preserved for
- 112 PCR assays.
- <sup>113</sup>Microscopy, long used in malaria diagnosis, can quantify parasite loads and identify
- <sup>114</sup>different *Plasmodium* species, which are essential for precise treatment choices [24,25].
- 115 However, its effectiveness depends significantly on the skill and experience of the
- 116 microscopist, making it unreliable in some contexts, and it can miss a substantial
- 117 number of true infections due to sub-optimal accuracy [26–28]. In contrast, Rapid
- 118 Diagnostic Tests (RDTs) offer a consistent and user-friendly option, enabling quick, on-
- 119 site diagnosis without specialized skills or equipment. RDTs have become widely used
- 120 in both point-of-care settings and population surveys due to their operational simplicity
- 121 and cost-effectiveness [29–33]. While the technique enhances access to diagnostics,
- 122 especially in remote areas, RDTs have lower sensitivity for detecting low-level infections
- 123 and cannot quantify parasite density or distinguish between *Plasmodium* species.
- 124 Additionally, current RDTs may detect antigens for over three weeks post-treatment,
- 125 leading to poor specificity and potential overestimation of malaria cases in high
- 126  $transmission$  areas  $[30,33,34]$ .
- 127 In contrast, polymerase chain reaction (PCR) assays are known for their high sensitivity
- 128 and specificity [35]. While conventional PCR assays typically provide qualitative
- 129 information on malaria infections, quantitative PCR (qPCR) can offer additional
- <sup>130</sup>quantitative measures of malaria parasite density [36,37]. Unfortunately, the widespread
- 131 use of PCR assays for population surveys is hindered by cost constraints and the need
- 132 for specialized expertise and infrastructure for implementation [35,38,39].
- 133 The increased focus on evidence-based strategies in malaria control also includes a
- 134 transition from broad subnational stratifications to more granular, fine-scale approaches
- <sup>135</sup>[6,10]. However, although current methods like RDTs and microscopy are favored for

136 their operational simplicity, their effectiveness in detailed risk stratification, which are 137 critical for targeting both clinical and sub-clinical infections for malaria elimination, 138 remains poorly understood. Some authors have also suggested that RDTs may have 139 vastly reduced performance in settings where the malaria burden has been significantly 140 reduced [40]. This calls for a rigorous evaluation and comparison of these methods 141 against highly sensitive techniques such as qPCR to refine malaria stratification 142 approaches for malaria elimination. Indeed, available evidence, including data from 143 Kenya and Tanzania, suggest that PCR assays are generally better at pinpointing main <sup>144</sup>malaria hotspots in communities than RDTs and microscopy [41,42]. The study from 145 Tanzania further showed that in subsequent treatment campaigns relying on RDT-146 based screening, ~45% of infections remain untreated, even if treatment is offered to all 147 members of households with an infected individual [42]. In the Kenyan study, the 148 authors went further to suggest that since detection of hotspots depends on the 149 sensitivity of diagnostic tools, health authorities working in malaria elimination settings 150 should consider using PCR to guide detection of the residual hotspots, as this provides 151 greatest opportunities to find asymptomatic individuals and sub-patent parasite

152 reservoirs in the communities [41].

153 All these studies clearly show that while sub-national stratification may be the most 154 effective approach to decide on how to allocate resources, the type of data used for 155 such epidemiological profiling matters significantly; especially when the stratification is 156 done at local-sub-district levels. In places like southeastern Tanzania, which has 157 experienced decades of sustained malaria interventions and progress, and where 158 robust entomological surveillance already exists [43], addition of detailed parasite 159 prevalence data from population-level surveys is required to enable more precise, fine-160 scale stratifications at both district and sub-district levels.

161 The aim of this study was therefore to generate a high-resolution population-level 162 survey map of *P. falciparum* prevalence in two districts in south-eastern Tanzania, and <sup>163</sup>compare the fine scale malaria risk strata obtained when using data from different test <sup>164</sup>methods, namely RDTs, microscopy and qPCR. The study also examined the 165 association between population-level parasite prevalence and the parasite densities as 166 determined by both qPCR and microscopy in the different study villages. Lastly, we

167 investigated the malaria detection capacity of RDTs and microscopy across villages with 168 varying parasite prevalences and densities.

### <sup>169</sup>**Methods**

## <sup>170</sup>**Study site**

171 The study was conducted in Morogoro region, in south-eastern Tanzania (Figure 1), in 172 the two districts of Kilombero (population:  $\sim$ 583,000; 8.2414°S, 36.3349°E; elevation: <sup>173</sup>~270m) and Ulanga (population: ~233,000; 8.9889°S, 36.6133°E; elevation: ~800m). <sup>174</sup>The average malaria prevalence in the Morogoro region has previously been estimated 175 to exceed 10%, with *P. falciparum* as the dominant malaria species [19,20,44]. The 176 main economic activities for residents include rice farming, sugarcane farming and 177 maize farming, though the area also has other food crops and large commercial tree 178 plantations (teak). The known annual rainfall range is 1200-1400 mm in the lower-lying 179 plains of Kilombero district, and 1400-2100 mm in the higher areas in Ulanga district <sup>180</sup>[45]. Approximately 90% of the rainfall occurs during the wet seasons between 181 December to April, with dry seasons typically lasting from June through September [45]. 182 The annual mean daily temperature is around  $27^{\circ}$ C in the lowlands and approximately 183 23°C in the highlands. Relative humidity averages from 75% in the lowlands to 80% in 184 the highlands.

<sup>187</sup>**Figure 1:** Study villages in Kilombero and Ulanga districts, south-eastern Tanzania.

## <sup>189</sup>**Study design, procedures and survey tools**

<sup>190</sup>The cross-sectional surveys were conducted over two consecutive years, from 2022 to

191 2023, covering the transition from the end of rainy seasons to the peak of dry seasons.

192 Villages were randomly selected from each district, and sample sizes were

- 193 proportionately determined based on the population of each village using the Cochran
- 194 formula adjusted for finite populations [46–48]. The expected prevalence varied
- 195 depending on the village and was derived from previous surveys and health centers
- 196 within each village. Based on the estimated sample size mentioned above,
- 197 representative households were selected by systematically randomizing the names of
- 198 all households obtained from the respective village administrations.

<sup>199</sup>The screening criteria included individuals aged 5-60 years who had not taken malaria <sup>200</sup>medications in the preceding two weeks. This precaution aimed to prevent potential 201 overestimation by RDTs, as they may detect residual traces post-treatment [49]. 202 Individuals needing special medical attention, such as pregnant women, were excluded 203 from the study. Each consenting individual undergoing malaria screening was assigned 204 a unique identity number that was also linked to their corresponding household ID. On-205 site malaria diagnosis was conducted using: 1) RDTs via finger prick, 2) creating thick 206 and thin blood smears, and 3) collecting 3-5 dried blood spots (cycles) on Whatman<sup>TM</sup> 207 filter paper cards. Subsequently, these samples were transported to the reference <sup>208</sup>laboratory for microscopy and qPCR analysis**.** For children under five years, only 209 screening with RDTs was done for prevalence estimations and not used for strata

210 comparisons.

### <sup>211</sup>**Ethical considerations, survey team, and trainings**

212 Permission to conduct this study was obtained from the Ifakara Health Institute Review

213 Board (Ref: IHI/IRB/No: 1/2021) and the National Institute for Medical Research-NIMR

<sup>214</sup>(NIMR/HQ/R.8a/Vol. 1X/3735). Additionally, approvals were obtained from regional,

215 district, ward, and respective selected village authorities before commencing the

216 surveys, given the screening was done at centralized location in each village. Written<br>217 informed consent was obtained from individual adult participants (and parents or

<sup>217</sup>informed consent was obtained from individual adult participants (and parents or

218 guardians of those aged below 18) on the day before the actual testing. The study team

219 consisted of 11 members, including three molecular laboratory technologists, four

220 licensed medical laboratory microscopists, two licensed clinical officers, and two social

221 scientists. Prior to the survey commencement, a five-day training session was

222 conducted at the Ifakara Health Institute laboratory. This training covered explanations

223 of the study protocols, pilot implementations, procedures for protecting human

224 participants, quality assurance and training on data collection tools.

## <sup>225</sup>**Tests using malaria rapid diagnostic tests (RDTs)**

226 A small blood drop obtained through a finger prick was collected onto the RDTs (SD<br>227 Bioline Ag Pf/Pan), following the manufacturer's instructions. The buffer solution was Bioline Ag *Pf*/Pan), following the manufacturer's instructions. The buffer solution was

228 applied according to standard RDTs procedures and left on the bench surface for up to

- 229 20 minutes. The type RDT used were capable of detecting *P. falciparum* infections by
- 230 targeting histidine-rich proteins 2, which react on the *Pf*-line. Additionally, they could
- 231 detect *P. malariae* and *P. ovale* by targeting glycolytic lactate dehydrogenase,
- 232 expressed by the Pan-line on RDTs [30]. The RDT results were recorded on a paper
- 233 form, and any individuals who tested positive for malaria were promptly treated with
- 234 Arthemether Lumefantrine (ALu), following Tanzania's national malaria treatment
- 235 guidelines [50].

#### <sup>236</sup>**Tests using microscopy**

237 Thick and thin blood smears were created in the field, stained with 10% Giemsa for 15 <sup>238</sup>minutes then examined for the presence of malaria parasites under oil immersion at 239 100X magnification [47,51,52]. Two experienced microscopists independently read the<br>240 slides, and discrepancies between them were resolved by a third, more experienced slides, and discrepancies between them were resolved by a third, more experienced 241 microscopist. They read the thick smear first, and if an infection was detected, the thin 242 smear was read to identify parasite species. The presence of both asexual and sexual <sup>243</sup>malaria parasite stages discriminating *P. falciparum*, *P. malariae*, and *P. ovale* was 244 recorded. Asexual stage parasites were counted per 200 white blood cells and <sup>245</sup>assuming 8000 WBC/μL [53]. The mean count of malaria parasite by microscopy 246 between the two readers was calculated and confirmed by the third reader.

## <sup>247</sup>**Tests using real-time qPCR assays**

248 A representative sample of approximately two thirds of all samples was randomly 249 selected from each village and screened further by quantitative polymerase chain 250 reaction (qPCR) i.e. 4905 samples out of the total 7628 samples. Out of five spots 251 created on the Whatman<sup>™</sup> filter paper card, three spots of DBS were used for DNA<br>252 extraction using Quick-DNA™ Miniprep plus kit (Zymo Research,USA) [54], and elut extraction using Quick-DNA<sup>TM</sup> Miniprep plus kit (Zymo Research, USA) [54], and eluted <sup>253</sup>with50 μL of elution buffer, stored at -20°C for further detection and quantification of *P.*  <sup>254</sup>*falciparum* infections using probe-level allele-specific quantification (PlasQ)-multiplex <sup>255</sup>qPCR assays protocols [37,55,56]. The detection and quantification of *P. falciparum* 256 parasites were performed using the Bio-Rad CFX96 real-time PCR system (Bio-Rad<br>257 Laboratories, USA) [55] and analyzed with Bio-Rad CFX maestro software. The qPCI Laboratories, USA) [55] and analyzed with Bio-Rad CFX maestro software. The qPCR 258 reaction, PlasQ primers and probes mix, are summarized in supplementary online table

259 1& 2. DNA amplification processes included: activation at 95°C for 1 min, denaturation 260 at 95 $\degree$ C for 15 seconds, and annealing and elongation at 57 $\degree$ C for 45 seconds for 45 261 cycles, followed by melting [55].

- <sup>262</sup>The qPCR assays were run with positive controls (samples with confirmed *P.*
- <sup>263</sup>*falciparum*) and a non-template control (samples with no *P. falciparum* as negative
- 264 control). For absolute parasite quantification, the WHO international standard for *P.*
- <sup>265</sup>*falciparum* nucleic acid amplification techniques were used (WHO reference from
- 266 NIBSC#04/176) [37]. The standard was reconstituted following the manufacturer's
- 267 instructions and serially diluted in the range of 100,000 parasites/μL to 0.01 and
- 268 analyzed in triplicates.
- 
- 269 During the qPCR assay, the prepared standards were run together with unknown<br>270 Samples, and at the end of the assay, the standard curve and samples were norm samples, and at the end of the assay, the standard curve and samples were normalized
- 271 and analyzed with Bio-Rad CFX maestro software. The obtained normalized Ct values
- 272 of the samples and the linear regression equation derived from the standard curve were
- 273 used to calculate the parasites density of the unknown samples, expressed as parasites
- <sup>274</sup>per microlitre (parasites/μL) of blood.

## <sup>275</sup>**Data analysis**

- 276 All results from RDTs, microscopy, and qPCR were entered into the Open Data Kit
- <sup>277</sup>(ODK) system [57], and subsequently downloaded as an excel file for further cleaning.
- 278 The datasets for RDTs, microscopy, and qPCR results were merged based on the
- 279 participant's ID using the Pandas Python package [58].
- 280 Generalized linear models (GLM) were used to evaluate the association between
- 281 malaria infection risk and the variables of age and gender in a univariate analysis, run in
- 282 Python using the stats model package [59]. Additionally, to evaluate the performance of
- 283 RDTs and microscopy in fine-scale malaria stratifications compared to qPCR, their<br>284 agreement was tested using Kappa statistic [60], and the resulting Kappa values
- agreement was tested using Kappa statistic [60], and the resulting Kappa values
- 285 interpreted as follows:  $\kappa \Box \langle \Box 0.20$  as poor agreement, 0.21–0.40 as fair, 0.41–0.60 as
- <sup>286</sup>moderate, 0.61–0.80 as substantially good and 0.81–1 as almost perfect agreement
- 287 [61]. In addition, the positive predictive value (PPV) for RDTs and microscopy was
- 288 computed, using qPCR results as the reference, per village, as (proportion of positive

289 test results that are actually true positives, estimated as PPV = True Positives / (True 290 Positives + False Positives)). Fine-scale stratification by villages using data from qPCR, 291 RDT, and microscopy were used to generate the prevalence maps using quantitative <sup>292</sup>Geographic Information System (qGIS) software, allowing visualization of malaria 293 prevalence across villages. Additionally, the risk maps were created using inverse 294 distance weighting (IDW) interpolation techniques. This method helped to estimate 295 malaria risk by spatially interpolating the prevalence data, which provided a continuous 296 surface of malaria risk across the study area.

297 The geometric mean of parasite density estimated by microscopy and qPCR was 298 computed, and statistically compared the parasite densities between gender and age 299 groups. The non-parametric Mann-Whitney statistics were used to compare the parasite 300 densities between two categorical groups, while Kruskal-Wallis statistical tests were 301 used to compare more than two categorical groups [62,63]. For example, differences in 302 parasite densities between age groups were tested using Kruskal-Wallis statistics, and if 303 statistically significant, the Mann-Whitney statistics were applied for pairwise statistical 304 significance tests. All analyses that compared parasite densities excluded the negative 305 class and focused solely on investigating parasite density distribution among malaria-306 positive patients. Lastly, to test for statistical correlations between parasite prevalence<br>307 and parasite densities estimated by both qPCR and Microscopy, non-parametric and parasite densities estimated by both qPCR and Microscopy, non-parametric 308 Spearman's rank correlation tests were employed [64]. Additionally, logistic regression <sup>309</sup>model was also used to assess the probability of diagnostic tools to detect malaria 310 infections at various parasite densities.

### <sup>311</sup>**Results**

## <sup>312</sup>**Baseline study population.**

<sup>313</sup>This survey covered 35 villages and 93 sub-villages across Ulanga and Kilombero

314 districts. A total of 7,628 participants (>5 years) were recruited upon consent and tested

315 for malaria using RDTs and microscopy, with 64.3% (4,905) of them also tested by

316 qPCR (Figure 2). Males comprised 38% of the study population, while females made up

<sup>317</sup>62%. Among the participants, 35% were school-aged children (5-15 years), and 65%

<sup>318</sup>were aged 16 years and above (Table 1). For children under five years, for whom

- 319 screening was conducted with only RDTs to estimate the burden, the results are not
- 320 reported here.

<sup>322</sup>**Figure 2:** *Schematic representation of the study sampling procedures* 

#### <sup>323</sup>**Table 1**: Baseline characteristics of the study populations

### <sup>325</sup>**Malaria prevalence by RDTs, Microscopy and qPCR**

326 In the Ulanga district, malaria transmission was found to be high by both qPCR and

<sup>327</sup>RDTs, with *P. falciparum* prevalence rates of 53.89% [95% CI, 52.06-55.72] and

<sup>328</sup>38.35% [95% CI, 36.92-39.79] respectively. However, microscopy categorized it as

329 moderate, with a prevalence rate of 26.07% [95% CI: 24.77-27.36] (Table 2). Within this

<sup>330</sup>moderate to high transmission strata in Ulanga, males had a significantly higher

331 prevalence of malaria compared to females. The odds of malaria infection in males

332 compared to females were estimated as 1.54 [95% CI: 1.36-1.74] ( $P < 0.001$ ) by RDTs,

<sup>333</sup>1.45 [95% CI: 1.27-1.66] (P < 0.001) by microscopy, and 1.54 [95% CI: 1.36-1.74] (P <

334 0.001) by qPCR (Table 2). All tests - RDTs, microscopy, and qPCR - indicated that

335 school-age children (5-15 years) had a significantly higher prevalence of malaria

336 infections than the other age groups (Table 2).

337 In Ifakara council, within the Kilombero district, both RDTs and microscopy categorized

338 the area as a low risk stratum, with observed prevalence rates of 2.68 [95% CI: 2.12-

339 3.24] and 1.84 [95% CI: 1.37 – 2.30], respectively (Table 3). However, qPCR classified

340 Kilombero district as a moderate risk stratum with a prevalence rate of 8.77 [95% CI:

341 7.55-9.99] (Table 3). Notably, there were no statistically significant differences in

<sup>342</sup>malaria infection risk between males and females in this low to moderate transmission

343 setting, as indicated by both RDTs (Odds prevalence 1.51% [95% CI; 0.97, 2.33],

- <sup>344</sup>P=0.065) and microscopy (Odds prevalence 1.33% [95% CI; 0.78, 2.25], P=0.293), as
- 345 well as qPCR (Odds prevalence 1.09% [95% CI:  $[0.80 5.67]$ , P = 0.567). Additionally,
- 346 school age children (5-15 years) exhibited a significantly higher risk of malaria infections
- 347 compared to those above 15 years old, as demonstrated by both RDTs, microscopy,
- 348 and PCR (Table 3).

# <sup>349</sup>**Micro-stratification of malaria risk using data collected by qPCR, RDTs, and**

- <sup>350</sup>**microscopy**
- 351 Significant variability in malaria infections was observed at the individual village level,
- 352 with prevalence rates ranging from 0% to over 50% across the study area (Figure 3 &
- 353 Table 4). Additionally, the method used to test for malaria significantly impacted the risk
- 354 categorization of villages. Among the 35 villages surveyed, qPCR data indicated that
- 355 only one village (1.2% of all villages) had very low malaria prevalence (PfPR  $<$  1%). In
- 356 contrast, RDTs identified 12 villages (34.3% of all villages) and microscopy identified 11
- 357 villages (31.4% of all villages) as having very low prevalence. For moderate
- 358 transmission, qPCR, RDTs, and microscopy categorized 15, 9, and 8 villages,
- 359 respectively. For high transmission, gPCR identified 14 villages, RDTs identified 8, and
- <sup>360</sup>microscopy identified 6. Notably, qPCR detected more malaria infections than RDTs
- 361 and microscopy, resulting in many villages being classified into higher transmission
- 362 categories.
- 363 Overall, using qPCR data, over 80% of the villages were classified as moderate to high
- 364 risk, significantly higher than the 48% classified by RDTs and 40% by microscopy.
- 365 Conversely, while only 17% of the villages were classifiable as having low or very low
- 366 malaria risk based on qPCR data, as high as 51% and 60% of the villages were
- 367 classified into these same categories based on RDT and microscopy data (Table 4 and
- 368 Figure 4)

<sup>389</sup>**Figure 4**: *Percentage of villages categorized by different testing methods as either very*  low risk, low risk, moderate risk or high risk (total number of villages = 35).

## <sup>391</sup>**Comparison of the perfomance of RDTs and microscopy relative to qPCR**.

- 392 In this comparative analysis, only samples tested by all three methods—PCR, RDTs,
- 393 and microscopy—were included, totaling  $64.3\%$  (n = 4905) of the samples (Table 5).
- <sup>394</sup>Among these, qPCR identified 1712 (34.9%) as positive, whereas RDTs and
- 395 microscopy classified 1289 (26.3%) and 843 (17.2%) positives, respectively (Table 5).

- 396 A substantial number of positive samples, otherwise detectable by qPCR, were missed
- 397 by both RDTs and microscopy, suggesting the existence of subpatent infections (table 5
- 398 and Figure 5). Of all samples analyzed by qPCR, RDTs, and microscopy, 647 out of
- <sup>399</sup>4,905 (13.2%) were categorized as positive by all three methods (Figure 5).
- 400 Interestingly, qPCR classified 56 out of 4,905 (1.1%) samples as negative, while both
- <sup>401</sup>RDTs and microscopy agreed they were positive (Figure 5). Similarly, the same
- 402 proportion was agreed upon by qPCR and microscopy as positive, while RDTs
- 403 classified them as negative. Microscopy classified 415 out of 4,905 (8.5%) samples as
- 404 negative, while both RDTs and qPCR agreed they were positive.

405 **Table 5:** Overall prevalence in the 35 surveyed villages estimated using qPCR, RDTs, 406 and microscopy. Additionally, the table summarizes the proportion of malaria positive

406 and microscopy. Additionally, the table summarizes the proportion of malaria positive<br>407 samples missed by RDTs and microscopy when qPCR is used as the reference.

samples missed by RDTs and microscopy when qPCR is used as the reference.

### **Proportion of missed positives when qPCR is the reference**

408

409 Both RDT and microscopy missed several infections otherwise identified by qPCR. This

410 category of false negatives included cases where qPCR identified a sample as positive,

411 but microscopy identified it as negative, cases classified as positive by qPCR but

412 negative by RDTs, and cases where RDTs indicated positive results while microscopy

413 indicated negative result. Out of the 1712 positives detected by qPCR, RDTs missed

- <sup>414</sup>650 (37.97%) and microscopy missed 1009 (58.9%) (Table 5). Additionally, when
- 415 comparing microscopy to RDTs, microscopy failed to detect 45.46% (586/1289) of
- 416 malaria infections detected by RDTs. RDTs correctly identified 1062 (62.03%) samples

417 as true positives, while microscopy identified 703 (41.06%) as true positives (Table 6).

418 Furthermore, RDTs misclassified 227 (7.10%) samples as false positives, while

<sup>419</sup>microscopy misclassified 140 (4.38%) (Table 6).

**Figure 5:** *The Venn diagram illustrates positive samples detected exclusively by a* 

422 specific tool while the other two missed them (qPCR only: 594 positive, RDT only: 171<br>423 positive, Microscopy only: 84 positive). Additionally, it shows intersections indicating

*positive, Microscopy only: 84 positive). Additionally, it shows intersections indicating* 

*positive detection by two tools when one detects negative (qPCR & RDT: 415 positive;* 

*qPCR & Microscopy: 56 positive; RDT & Microscopy: 56 positive). It also indicates* 

*intersections where all tools detect positive samples (qPCR, RDT, & Microscopy: 647 positive).*

<sup>428</sup>**Table 6**: Evaluation metrics for assessing the performance of RDTs and microscopy relative to qPCR during the fine-scale 429 stratification of malaria risk in Ulanga and Kilombero districts, south-eastern Tanzania.

# <sup>430</sup>**Positive predictive values (PPVs), sensitivity, specificity, and agreement of RDTs**  <sup>431</sup>**and microscopy when compared to qPCR**

432 Considering qPCR as the benchmark, the sensitivity (the proportion of actual positives 433 which were correctly identified as such) of RDTs was 62.0% [95% CI: 60.0-64.2], while 434 that of microscopy was 41.0% [95% CI: 38.8 - 43.4]. The specificity (proportion of actual 435 negatives which were correctly identified as such) was 92.9% [95% CI: 92.00-93.7] for 436 RDTs and 95.6% [95% CI: 94.9- 96.3] for microscopy (Table 6). Overall, the positive 437 predictive value (PPV), i.e. the probability that individuals with a positive test result 438 actually have the disease, was 82.4% [95% CI: 80.3 -84.4] for RDTs and 83.4% [95% <sup>439</sup>CI: 80.8-86.0] for microscopy (Table 6). Importantly however, the PPV for both RDTs 440 and microscopy varied with malaria endemicity, generally increasing with prevalence, 441 ranging from less than 20% in very low transmission areas to over 80% in high 442 transmission areas (Figure 06).

<sup>444</sup>When considering the micro-strata generated using qPCR data, the PPV of RDTs and 445 microscopy started at 0% in very low risk strata and gradually increased to >80% as 446 villages shifted towards high risk strata (Figure 6A). However, when referring to the 447 strata generated using RDTs data (Figure 6B), the PPV of both RDTs and microscopy 448 started at 20% in very low risk strata and gradually increased to >80% in high-risk 449 strata. The agreement between RDTs and  $qPCR$  was good (Kappa value = 0.58 [95% 450 CI: 0.56-0.61]), while the agreement between microscopy and qPCR showed fair 451 agreement (Kappa value = 0.42 [95%CI: 0.39-0.44]), (Table 6).

453 The sensitivity of both RDTs and microscopy varied by age, where RDTs sensitivity was <sup>454</sup>higher for school-aged children (>80%) and dropped to 75% and 60% for 16-20 years 455 and >20 years, respectively (Figure 6C). A similar trend of sensitivity was observed for <sup>456</sup>microscopy (Figure 6C), indicating that RDTs and microscopy perform better in 457 detecting malaria in school-aged children compared to adults.

458 The relationship between parasite density and the malaria detection probability by RDTs 459 and microscopy was also examined. In this analysis, the probability of RDTs detecting

- $460$  positive malaria infections was maximized reaching 1 at 100 parasites/ $\mu$ L, where the
- 461 **logistic regression (logit (p)) model saturated (Figure 6D).** At this density in contrast, the
- 462 probability of microscopy to detect malaria infections was only 0.85% (Figure 6D),
- 463 suggesting higher sensitivity of RDTs vs microscopy.

<sup>465</sup>**Figure 6:** *Estimates of the positive predictive values (PPVs) of RDTs and microscopy at*  <sup>466</sup>*different malaria endemicities across the study villages, defined based on either qPCR*  <sup>467</sup>*data (A) or RDT data (B). Panel C) illustrates the trend of sensitivity of both RDTs and*  <sup>468</sup>*microscopy relative to age groups. Panel D) displays the detection probability of both*  <sup>469</sup>*RDTs and microscopy relative to the parasite density estimated by qPCR.*

#### <sup>470</sup>**Parasites density estimates and their correlations with** *Plasmodium* **prevalence**

471 Further, asexual parasite densities estimated by both microscopy and qPCR were 472 investigated and compared across different sex and age groups using Mann-Whitney 473 statistics for two categories and the Kruskal-Wallis statistical test for more than two 474 categories. Overall, PCR was capable of detecting approximately 100 fold lower 475 parasite densities compared to microscopy. The geometric mean asexual parasite 476 density estimated by microscopy was 2206.4 parasites/μL (95% CI: 1976.7-2462.8), 477 while that estimated by PCR was 27.07 parasites/μL (95% CI: 23.23-31.54) (Table 7).<br>478 478 The asexual parasite density of infected individuals significantly differed between males 480 and females as estimated by qPCR ( $P < 0.001$ ), with males harboring a higher parasite 481 density compared to females, though similar trend was observed by microscopy, this 482 sex difference was not statistically detectable by microscopy ( $P = 0.11$ ). Importantly, the 483 geometric mean parasite density estimated by both microscopy and qPCR per village 484 demonstrated a significant positive correlation with the parasite prevalence of the 485 respective village. Thus, villages with high malaria prevalence also had high malaria 486 parasite densities compared to villages with lower prevalence (Figure 7C-F). 487 Considering qPCR-estimated geometric mean parasite densities, the Spearman rank 488 correlation score was 0.77 (P < 0.001) and 0.76 (P < 0.001) when the malaria 489 prevalence of the villages was estimated by qPCR and RDTs, respectively (Figure 7C & 490 7E). On the other hand, the Spearman rank correlation for the parasite density 491 estimated by microscopy was 0.55 (P  $<$  0.003) and 0.48 (P  $<$  0.012) for qPCR and 492 RDTs estimated prevalence of the villages, respectively (Figure 7D & 7F). 493 When parasite density by age groups were analyzed, both microscopy and qPCR 494 revealed a significant difference in estimated malaria parasite densities between age 495 groups based on Kruskal-Wallis statistics (P < 0.001) (Table 7). Pairwise tests by Mann-<sup>496</sup>Whitney statistics revealed that school-aged children (5-15 years old) harbored a higher 497 parasite density than those 16 years old and above ( $P < 0.001$ ) as indicated by both 498 microscopy and qPCR (Figure 7A & 7B).

<sup>499</sup>**Table 7:** Parasite densities by gender and age as estimated using Microscopy slides and quantitative PCR assays 500

### <sup>506</sup>**Discussion**

507 In malaria-endemic countries, data-driven risk stratification is increasingly used at 508 district or higher regional levels to guide intervention strategies and optimize resource 509 allocation. Additionally, the geographical variations in levels of endemicities and the shift 510 towards elimination in some settings necessitates finer resolution for optimal resource 511 allocation [6,10,72]. In most settings in Africa, the data used for epidemiological 512 stratification of malaria typically comes from rapid diagnostic tests (RDTs) or <sup>513</sup>microscopy-based testing, which despite wide scale availability and low operational 514 costs, often perform poorly in low transmission settings [41,73,74]. While direct 515 comparisons of these diagnostic tools for fine-scale stratification are currently limited, 516 selecting the most appropriate data sources and testing methods is crucial, as different 517 methods can yield significantly different results depending on endemicity, particularly in 518 elimination settings. Even without alternative testing methods, data users and decision-<sup>519</sup>makers need to understand the limitations of their selected approaches, especially the 520 weaknesses of current dominant data sources like RDTs or microscopy. In this study, 521 we conducted a high-resolution survey of *P. falciparum* malaria in two Tanzanian 522 districts, comparing fine-scale strata obtained using RDTs, microscopy, and qPCR 523 assays. The findings will provide the necessary evidence to the malaria programs at 524 national and district levels on how RDTs, microscopy, and qPCR compare when used at 525 local levels. Moreover, the findings demonstrate that selection of appropriate test 526 methods is essential for more precise resource allocation and improved understanding 527 of disease patterns.

<sup>528</sup>The findings highlight significant variability in malaria risk at a fine scale. Within less 529 than 150 kilometers, malaria prevalence estimates ranged from 0% to over 50% across 530 contiguous villages in an area broadly classified as moderate risk ( $\sim$ 17% PfPR) by 531 recent government stratification [44]. Such fine-scale variability is not uncommon and 532 has been observed in several other settings [75]. In one study in Madagascar, there <sup>533</sup>was a tenfold difference of malaria prevalence within a radius of less than 50 kilometers 534 [76]. For precise micro-stratifications, this study emphasizes the importance of carefully 535 selecting diagnostic tools, especially for local malaria elimination efforts. Our findings 536 indicate that RDTs and microscopy have poor positive predictive values, which can be

537 even less than 20% in villages with very low and low transmission as the proportion of 538 truly infected individuals is very small compared to non-infected persons. There were 539 also significant discrepancies in the resulting micro-strata depending on the test method 540 used. For instance, among the 35 surveyed villages, RDTs and microscopy classified 541 12 and 11 as very low and 6 and 10 as low risk strata, respectively, while  $qPCR$ 542 identified only 1 village as very low and 5 as low transmission. This means RDTs and 543 microscopy classified majority of the villages as very low to low risk while qPCR 544 classified most villages as moderate to high risk (Table 4).

545 Clear demarcation of areas with very low to low risk versus those with moderate to high 546 risk is essential, particularly in the push towards elimination. As countries increasingly 547 adopt data-driven decision-making for malaria control, there is a risk of improper 548 resource allocation or premature withdrawal of effective interventions from localities 549 erroneously deemed as nearing elimination. Local authorities need to decide which data 550 to use for local-level micro-stratification and whether RDTs, commonly used for broader-551 scale sub-national stratification, suffice for fine-scale local decision-making. Previous 552 evidence has shown that hotspots identified by RDTs are less stable than those 553 identified by microscopy and PCR [41]. Hotspots of febrile malaria infections are also <sup>554</sup>generally unstable and variable over geographical spaces, while hotspots of 555 asymptomatic cases tend to be more permanent and can be more practically targeted 556 for transmission control [77]. In this current study, we also found significant positive 557 correlations between malaria parasite densities and malaria prevalence in southeastern 558 Tanzania, emphasizing the need to incorporate tests that depict sub-microscopic 559 infections into malaria stratification and decision making to better target the hotspots. As 560 already reported in other studies, villages in our study area, which were classified as 561 low transmission areas had lower geometric mean parasite density compared to those 562 with higher transmission rates.

563 Our findings, benchmarked against qPCR, reveal limited detection capabilities of RDTs 564 and microscopy in overall fine-scale stratifications, especially in low transmission 565 settings. Previous studies have emphasized the usefulness of routine hospital data for <sup>566</sup>micro-stratifications [8,10,78,79]. However, evidence indicates that both microscopy and 567 RDTs are less effective in identifying stable febrile malaria hotspots, except for

568 asymptomatic hotspots, which are reliably identified by microscopy [77], however still 569 not stable when transmission is low [80]. Our research underscores the importance of 570 identifying subclinical infections using sensitive tools to advance malaria elimination, 571 particularly through fine-scale population surveys. Additionally, there is evidence 572 suggesting potential benefits from integrating hospital and school-age children survey 573 data or even antenatal care centers [2,9]. Nevertheless, these approaches heavily rely 574 on rapid diagnostic tests (RDTs) as the primary tool for malaria detection. While the <sup>575</sup>World Health Organization (WHO) recommends monitoring RDT performance alongside 576 microscopy, our study is particularly relevant as we have directly compared the fine-577 scale stratification capabilities of RDTs, microscopy, and qPCR at a fine scale.

578 This study demonstrated overall good agreement between RDTs and qPCR, while 579 microscopy showed fair agreement. However, RDTs missed over 38% of malaria 580 infections, particularly among adults over twenty years old, who were found to harbor 581 lower parasite densities compared to those under twenty years old. However, RDTs 582 remain useful in testing fever-positive malaria cases in hospitals and are widely 583 employed in population surveys due to their cost-effectiveness and ease of 584 implementation [32]. As evidenced in this study, carefully re-consideration of using 585 RDTs for finer-scale mapping and intervention planning at sub-district level should be a 586 priority. Similarly, microscopy missed >50% of the malaria infections detected by qPCR, 587 which is consistent with previous studies, including a meta-analysis of 42 studies, which 588 showed that microscopy misses over 50% of malaria infections [26,66]. Operational 589 challenges, such as the level of expertise required for accurate detection and the need 590 for electricity and precise sample handling procedures, contribute to these limitations. 591 Interestingly, microscopy underestimated malaria risk by classifying more villages as 592 low strata compared to qPCR. Nonetheless, microscopy still plays a crucial role when 593 used in conjunction with tools like RDTs, providing valuable information about malaria 594 parasite densities [81–83]. Here, we estimate a 100-fold higher parasite density when 595 measured by microscopy compared to densities measured by qPCR, consistent with 596 similar trends observed in previous studies [55]. The findings of this study also indicate 597 that the false-negative rate of microscopy decreases with increasing parasite density, a 598 pattern observed in other studies too [81].

The analysis also revealed variations in parasite densities across different age groups, with school-age children (5-15 years old) exhibiting higher parasite densities compared 601 to individuals aged 16 and above. Notably, our study identified a reduced sensitivity of 602 both RDTs and microscopy among adults aged over 16 years, consistent with findings from prior studies conducted before 2015 in various regions [84–91]. It is possible this 604 pattern is driven by the age-related differences in malaria parasite prevalence, which was also observed (Table 3). Furthermore, our findings suggest that this trend may be 606 attributed to the lower parasite density estimates observed in adults within the study (Figure 7A & 7B). Significantly, our research provides valuable insights, highlighting the potential implications of these trends, particularly in fine-scale mapping scenarios, where RDTs and microscopy may underestimate stratifications at very low and low transmission strata, with qPCR serving as the reference standard in this study.

611 Ultimately, this study underscores the potential need to expand the use of molecular<br>612 approaches such as qPCR to achieve more precise mapping of malaria infections. approaches such as qPCR to achieve more precise mapping of malaria infections, <sup>613</sup>which could reduce false negatives and facilitate more precise resource allocations. 614 However, qPCR has operational challenges, including the need for well-designed 615 infrastructure, high costs, and expertise, and it is not portable for remote areas [82]. 616 Efforts are underway to develop portable qPCR technologies, but cost and expertise<br>617 Femain significant barriers. To address these gaps, NMCPs should develop innovative remain significant barriers. To address these gaps, NMCPs should develop innovative 618 plans, which might include: a) centralized facilities receiving and processing qPCR 619 samples and then doing such surveys only infrequently, say every 3 years; b) partnering <sup>620</sup>with local research organizations to support the high accuracy evaluations with nucleic 621 acid based tests. A related point to emphasize is the overall need for highly-sensitive,<br>622 cost-effective, and potentially reagent-free tools that align with the economic context o cost-effective, and potentially reagent-free tools that align with the economic context of <sup>623</sup>malaria-endemic settings. Recent innovations such as the saliva-based tests [92] or the 624 use of Infrared spectroscopy (IR) and machine learning (ML)  $[82,93]$  have shown 625 promise in detecting malaria infections at sensitivities equivalent to PCR, but further 626 research are needed before these technologies can be routinely deployed. Such 627 reagent-free assays like the IR-AI based approaches would be particularly 628 transformative for scaling up effective micro stratification of malaria risk in Africa. <sup>629</sup>This study also raised some important new questions. For example, it is baffling to

630 observe that areas with low transmission also have persistently low parasite densities

- 631 despite individuals having low immunity compared to those in higher transmission
- 632 settings who acquire immunity and become protective. Studies have demonstrated that
- 633 in low transmission areas, highly virulent parasites are more exposed to facilitate
- <sup>634</sup>malaria transmission by mosquitoes compared to low virulent ones [26,94–96].
- <sup>635</sup>Consequently, high virulent parasites are detected and treated, leading to their removal
- $636$  from the population  $[26,94–96]$ . This leaves behind low virulent parasites that are less
- <sup>637</sup>exposed and maintain low densities, becoming symptomatic, undetectable, and
- <sup>638</sup>untreated [26,94–96]. This phenomenon may contribute to long-term parasite
- 639 transmission strategies, highlighting the importance of using highly sensitive tools for
- 640 screening [55,97,98].

641 One limitation of this study is its failure to consider factors that may contribute to the

- <sup>642</sup>broader heterogeneity of malaria infections in southeastern Tanzania. Future
- <sup>643</sup>investigations should delve into potential environmental, geographical, immunological or
- <sup>644</sup>genetic diversity of the parasite influences underlying this variability. Additionally, the
- <sup>645</sup>biological significance of missed infections by both RDTs and microscopy was not
- 646 explored. Consequently, the study did not estimate the transmission burden associated
- 647 with these undetected positive samples, nor assess the parasite densities necessary to
- 648 sustain transmission in the population.

## <sup>649</sup>**Conclusion**

650 As countries progress towards malaria elimination, fine-scale mapping of malaria risk 651 becomes increasingly important. This study highlights significant variability in village-<sup>652</sup>level malaria risk within and between districts in southeastern Tanzania, an area where 653 the scale-up of effective interventions has led to substantial progress, yet cases persist 654 despite high intervention coverage. Secondly, the study underscores the variable 655 performance of different testing methods in stratifying risk. While RDTs and microscopy, <sup>656</sup>the primary test methods used in low-income endemic settings and the main sources of 657 data for ongoing epidemiological stratification efforts, were effective in high-transmission<br>658 areas, they performed poorly in low-transmission settings, often classifying most areas, they performed poorly in low-transmission settings, often classifying most

659 villages as very low or low risk. In contrast, qPCR classified most villages as moderate

660 or high risk. These findings demonstrate the importance of using appropriate testing 661 methods for data-driven, fine-scale risk stratification to enhance targeted interventions <sup>662</sup>aimed at reducing and eliminating malaria. The study underscores the need for <sup>663</sup>improved testing approaches that are both operationally feasible and sufficiently 664 sensitive to enable precise mapping and effective targeting of malaria in local contexts. <sup>665</sup>More importantly, public health authorities must recognize the strengths and limitations 666 of their available data when planning local stratification or making decisions. While 667 innovation for more effective strategies is ongoing, sensitive molecular tools like qPCR, <sup>668</sup>despite their operational challenges, will be crucial for accurate malaria risk mapping <sup>669</sup>and intervention planning, especially in settings with significantly reduced risk. Going 670 forward, developing new tools that balance operational costs and sensitivity, particularly 671 in low transmission settings, will be essential for effective malaria control and eventual 672 elimination.

- 697 This work was supported in part by the Bill & Melinda Gates Foundation (Grant number
- 698 Grant No. OPP 1217647 and Grant No. INV-002138 to Ifakara Health Institute). Under
- <sup>699</sup>the grant conditions of the Foundation, a Creative Commons Attribution 4.0 Generic
- <sup>700</sup>License has already been assigned to the Author Accepted Manuscript version that
- 701 might arise from this submission. Support was also received from Rudolf Geigy
- <sup>702</sup>Foundation through Swiss Tropical & Public Health Institute (to Ifakara Health Institute),
- <sup>703</sup>Howard Hughes Medical Institute (HHMI) and Gates Foundation (Grants: OPP1099295)
- 704 awarded to FOO and HMF, Royal Society (Grant No ICA/R1/191238 to SAB University
- 705 of Glasgow and Ifakara Health Institute). Academy Medical Science Springboard Award
- 706 (ref: SBF007\100094) to FB.

### <sup>707</sup>**Ethics approvals**

- <sup>708</sup>This work was approved under Ifakara Health Institute Review Board (Ref: IHI/IRB/No:
- <sup>709</sup>1 2021) and the National Institute for Medical Research-NIMR (NIMR/HQ/R.8a/Vol.
- 710 1X/3735). Permission to publish this work has been granted with reference No: BD.
- <sup>711</sup>242/437/01C/6.

### <sup>712</sup>**Data availability**

- <sup>713</sup>The dataset supporting the findings is available upon a reasonable request, which can
- 714 be directed to either the corresponding author, the Ifakara Health Institute ethical review
- 715 board in Tanzania or National Health Research Ethics Committee in Tanzania with
- 716 reference to ethical clearance certificate of NIMR/HQ/R.8a/Vol. 1X/3735.
