

Supplementary Material For: Assessing the Impact of Non-Pharmaceutical Interventions on COVID-19: A Combined CCE and Quantile Regression Approach

Kaibalyapati Mishra

July 15, 2024

As I examine the impact of NPIs on COVID-19 outcomes in India, focusing on infection and deaths, the independent variables representing NPIs include stringency measures (ψ_s), containment measures (ψ_c), economic support measures (ψ_e), and overall government support measures (ψ_o), which is an aggregated index of the other three. The dependent variables are the weekly infection rates (I_t) and weekly death rates (D_t). Government spending on these measures can be represented as:

$$G_t = \psi_s \cdot C_s + \psi_c \cdot C_c + \psi_e \cdot C_e$$

where C_s, C_c, C_e are the respective costs associated with each type of measure. We don't mention C_o here though we use it in empirical estimation because C_s, C_c, C_e combined is C_o . Households derive utility from both consumption and health levels. The utility function is specified as:

$$U(C_{in}, C_{out}, H) = \alpha \ln(C_{in}) + \beta \ln(C_{out}) + \gamma H$$

where C_{in} denotes indoor consumption, C_{out} denotes outdoor consumption, and H represents the health level of the household. The health level is influenced by the infection rate (I_t) and the death rate (D_t), with the formulation $H_t = H_0 - \delta I_t - \lambda D_t$. This setup captures the trade-off households face between maintaining consumption activities and protecting their health during the pandemic.

To account for the lag between the implementation of government policies and their observed effects, the model employs dynamic programming. The value function $V_t(S_t)$ is maximized over the policy actions ψ , considering both current utility and the expected future utility. The Bellman equation is given by:

$$V_t(S_t) = \max_{\psi} [\alpha \ln(C_{in}) + \beta \ln(C_{out}) + \gamma H + \beta \mathbb{E}[V_{t+1}(S_{t+1})|S_t, \psi_t]]$$

The state transition incorporates the time lag τ , with the transition equation $S_{t+\tau} = f(S_t, \psi_t, \epsilon_t)$, where ϵ_t is a random error term.

The model defines the state transition probabilities to capture the impact of NPIs on infection and death rates. The probability of transitioning from one state S_t to another S_{t+1} is modeled as $\mathbb{P}(S_{t+1}|S_t, \psi_t) = \mathbb{P}(I_{t+1}, D_{t+1}|I_t, D_t, \psi_t)$. The infection dynamics are expressed as $I_{t+1} = I_t \cdot (1 + g(\psi_s, \psi_c, \epsilon_{I,t}))$, and the mortality dynamics are formulated as $D_{t+1} = D_t + h(\psi_s, \psi_c, \psi_e, \psi_o, \epsilon_{D,t})$.

The optimization problem faced by households is to choose the optimal levels of indoor and outdoor activities under the given NPIs to maximize their utility. This is represented as:

$$\max_{\{C_{in}, C_{out}\}} \{\alpha \ln(C_{in}) + \beta \ln(C_{out}) + \gamma (H_0 - \delta I_t - \lambda D_t)\}$$

This formulation integrates the trade-offs between consumption and health, considering the direct impact of NPIs on the infection and death rates, thus providing a comprehensive framework for analyzing the effectiveness of government interventions during the COVID-19 pandemic.
