# ABSTRACT

Evidence has linked head trauma to increased risk factors for neuropathology, including acute mechanical deformation of 1 2 the cortical sulcal fundus and, later, perivascular accumulation of hyperphosphorylated tau (p-tau) adjacent to these spaces related to chronic traumatic encephalopathy (CTE). Despite this, little is known about microstructural abnormalities and 3 cellular dyshomeostasis at the acute stage of mild traumatic brain injury (mTBI) in humans, particularly in the cortex. To ad-4 dress this gap in the literature, we designed the first architectonically-motivated quantitative susceptibility mapping (QSM) 5 study to assess regional patterns of positive (iron-related) and negative (myelin-, calcium-, and protein-related) magnetic 6 susceptibility in cortical regions of interest (ROI) following mTBI. Depth- and curvature-specific positive and negative QSM 7 values were compared between 25 males with acute (< 14 days) sports-related mTBI (sr-mTBI) and 25 age-matched male 8 9 controls across 34 cortical ROIs. Bilateral between-group analyses were conducted on specific ROI curvature bins (crown, bank, and fundus) as well as a combined curvature measure, across 21 cortical depths, for each ROI. Correlations between 10 positive and negative susceptibility were analysed for age, brain injury severity, and the number of days since injury. We 11 observed significant group differences in magnetic susceptibility for depth, curvature, and ROIs. Our results suggest a trauma-12 induced pattern of likely iron deposition preferential to superficial, perivascular-adjacent spaces in the sulci of the parahip-13 pocampal gyrus. Co-localised decreases in diamagnetism in the same region suggest dual pathology of neural substrates, 14 15 the biological mechanisms behind which remain speculative. Significant correlations were found between magnetic susceptibility and age, both in ROIs and cortical depths distinct from those showing sr-mTBI-related differences. Little to no re-16 17 lationship was observed between magnetic susceptibility and subjective markers of injury or injury latency. The coherence between our findings and pathognomonic patterns of misfolded proteins in trauma-related neurodegeneration is interest-18 ing, which may have implications for the role of brain iron in microstructural cortical tissue damage after a mild brain injury. 19

20 Further longitudinal research is needed to elucidate the long-term implications of our findings.

# 21 INTRODUCTION

Mild traumatic brain injury (mTBI) is responsible for up to 90% of the estimated 27-69 million annual incidents of traumatic brain 22 23 injury worldwide; <sup>1-3</sup> representing a ~USD \$400 billion global economic burden.<sup>4</sup> In addition to economic impacts, exposure to mild head trauma is a major public health concern. mTBI is associated with adverse mental health effects, cognitive decline, in-24 creased risk of neurodegenerative disease, <sup>5,6</sup> and premature mortality.<sup>7</sup> Repeated instances of brain trauma is a well documented 25 risk factor for the progressive tauopathy known as chronic traumatic encephalopathy (CTE), most often observed in athletes as a 26 result of participation in contact sports, or in military veterans from exposure to blast impacts.<sup>8-14</sup> mTBI is characterised by a pri-27 mary insult to the brain, affecting tissue microstructure and inducing a cascade of secondary cellular processes, transient states of 28 metabolic distress, and cellular dyshomeostasis.<sup>15</sup> The absence of discernible focal lesions or other macroscopic morphological ab-29 normalities means standard neuroimaging approaches are often insufficiently sensitive to detect mTBI pathology.<sup>16,17</sup> Advanced 30

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

neuroimaging methods extending beyond the scope of conventional medical practices may be used to identify the subtle, diffuse,
 and heterogeneous changes in brain structure. <sup>18,19</sup> Despite promising advances toward discovery of mTBI biomarkers, to date no
 specific markers of structural brain injury have been identified and assessments are thus restricted to clinical evaluations and self reported impairments in cognitive and physiological function. <sup>17,20</sup> These assessments may not accurately reflect objective mea sures of brain injury or recovery status, which can constrain intervention efficacy.<sup>20,21</sup>

Investigating the role of biomaterials involved in preserving neuronal homeostasis, including trace elements such as brain 36 iron, represents a promising direction for biomarker research. Iron is essential for proper brain function, and is a cofactor in various 37 neuronal processes including neurotransmitter-, myelin-, and DNA-synthesis, energy metabolism, and oxidative phosphorylation.<sup>22</sup> 38 Cellular concentrations are tightly regulated within neural tissue and dyshomeostasis has been linked to oxidative stress, DNA and 39 protein damage, inflammation, and ferroptosis (a form of iron-regulated cell death).<sup>23-25</sup> Evidence suggests iron overload is impli-40 41 cated in both secondary injury and the emergence of pathology downstream<sup>26</sup> including hyperphosphorylation of tau (p-tau),<sup>27</sup> 42 highlighting the direct interplay between elevated levels of iron and CTE-like processes. Histologically-validated co-localisation of iron with abnormal protein accumulations in progressive tauopathies has distinguished brain iron as a hallmark feature of degener-43 ative disorders such as Alzheimer's and Parkinson's disease (AD and PD, respectively)<sup>28,29</sup> and has been cited within neurofibrillary 44 tangles in CTE.<sup>30</sup> Despite evidence linking head trauma to increased risk factors for premature iron-related neuropathology<sup>31</sup> and 45 increased levels of brain iron in humans following mTBI,<sup>25</sup> the association between brain iron accumulation and the pathophysiol-46 ogy of acute sports-related mild traumatic brain injury (sr-mTBI) remains unclear. 47

Quantitative susceptibility mapping (QSM), an advanced magnetic resonance imaging (MRI) method, measures intrinsic 48 magnetic properties and spatial distributions of biomaterials and molecules (including iron, calcium, protein, and myelin) that are 49 related to brain tissue composition.<sup>32-37</sup> The magnetic susceptibility of these materials is proportional to the degree of magnetisa-50 tion exhibited in response to an external magnetic field, such as the main magnetic field of an MRI scanner ( $B_0$ ).<sup>38</sup> Differences in 51 magnetic field perturbation from dia- and para-magnetic compounds in brain tissue create inhomogeneities in the phase maps of 52 gradient-recalled echo (GRE) MRI sequences.<sup>39–41</sup> This mechanism generates contrast in QSM, thereby providing insights into the 53 architecture of the brain and enabling more accurate delineation of many structural boundaries than the corresponding GRE mag-54 nitude images.<sup>42</sup> Unlike traditional susceptibility-weighted imaging (SWI) from which QSM is derived, this approach can be used to 55 directly quantify the susceptibility of tissue within regions of interest (ROIs), serving as a close approximation of the constituent ele-56 ments. 43,44 Already integral to dementia research, 45-50 QSM can be extended to investigate potential susceptibility-related pathol-57 ogy resulting from acute sr-mTBI. 58

A limited number of studies have used QSM to quantify magnetic susceptibility in white matter and/or subcortical or global 59 grey matter, <sup>51–57</sup> or as a marker of cerebral venous oxygen saturation (SvO<sub>2</sub>). <sup>56,58,59</sup> QSM investigations of mTBI-related grey mat-60 ter alterations have focussed almost exclusively on deep grey nuclei as a proxy for injury effects and cellular degeneration. This is 61 due to the high density of iron in these nuclei related to elevated metabolic demand,<sup>26</sup> particularly in the globus pallidus, red nu-62 63 cleus, substantia nigra, putamen, dentate, caudate, and thalamus, relative to the cortical grey matter. <sup>60</sup> These deep grey matter sites are not only vulnerable to iron-mediated disorders<sup>61</sup> but also damage in mTBI.<sup>62</sup> However, studies using QSM to investigate 64 mTBI effects have largely overlooked the cortex. This complex structure is characterised by ridges (gyri) and grooves (sulci); curva-65 tures corresponding to the base (fundus) of these sulci are exposed to the greatest force during mTBI, a phenomenon referred to as 66 the 'water hammer effect.' 63 67

These cortical, microvascular-adjacent, regions most susceptible to mechanical deformation and injury in mTBI are also the primary loci of degeneration and tauopathy in CTE <sup>12,64</sup> and warrant careful investigation. The singular mTBI-QSM study to include cortical grey matter ROIs <sup>52</sup> was constrained by a macroscopic voxel-wise approach. Significantly more anatomical precision is needed to detect depth- or curvature-specific differences in magnetic susceptibility within the cortical mantle after mTBI. The cortex is likely excluded from investigation due to several methodological challenges primarily related to complex cortical architectonics. Firstly, differentiating myeloarchitecture, cytoarchitecture, and cortical laminae using ultra-high field, ultra-high resolution MRI (such as that acquired at 7T or higher), is a developing area in neuroimaging research. <sup>65</sup> Currently, however, most research institutions pri-

marily use MRI scanners with lower field strengths. Secondly, standard voxel-wise comparisons are naïve to the architectonics and distribution of cellular elements within the cortical layers; here, advanced analytic techniques are essential. At magnetic field strengths of 3T or lower, and supra-millimetre voxel resolutions, analysis of specific cortical laminae is inhibited; however, column-based analytic techniques <sup>66–69</sup> enable depth-wise investigations of magnetic susceptibility in the cerebral cortex and are already producing promising results in Alzheimer's research.<sup>67</sup>

To address these research gaps, we conducted the first architectonically-motivated QSM analysis of cerebral mTBI effects. 80 This study aimed to: 1) assess regional patterns of positive (iron-related) and negative (myelin-, protein-, calcium-related) magnetic 81 susceptibility as a marker of acute cortical pathology after sr-mTBI, and; 2) understand the relationship between magnetic suscepti-82 bility in the cerebral cortex and variables such as age, injury latency, and severity. Based on prior literature, we hypothesised that dif-83 84 ferences in susceptibility would likely be evident in the frontal and temporal cortices, which are reported to be susceptible to injury 85 in mTBI and are among the first to show degenerative effects of brain injury. We expected this distribution to be most prominent in the sulcal fundus due to increased vulnerability to trauma-induced deformation. Based on known effects of age on cortical iron 86 deposition in this age range, <sup>60</sup> positive susceptibility values were hypothesised to show a positive relationship with age; however, 87 88 correlation analyses remained largely exploratory and without specific a priori hypotheses.

# 89 MATERIALS AND METHODS

90 Approval for this study was granted by both The Auckland University of Technology Ethics Committee ((AUTEC) Date: 18/02/2022,

- 81 Ref: 22/12) and the Health and Disabilities Ethics Committee ((HDEC) Date: 18/02/2022, Ref: 2022 EXP 11078). The study was
- 22 conducted following the Declaration of Helsinki and all participants provided written informed consent prior to data collection. All
- 93 participants were provisioned a \$50NZD food voucher to acknowledge their contribution as well as a \$20NZD fuel voucher or taxi
- 94 chit to cover travel expenses related to MRI scan attendance.

### 95 Participants

Data from 25 male contact sports players (M = 21.10 years old [16-32], SD = 4.43) with acute sr-mTBI (< 14 days; M = 10.40 days, 96 SD = 3.03) and 25 age-matched male controls (M = 21.10 years old [16-32], SD = 4.35) were used for this observational, case-control 97 study (see Table 1). Clinical (sr-mTBI) participants were recruited through three Axis Sports Medicine clinics (Auckland, New Zealand) 98 and through community-based pathways including referrals from healthcare professionals and sports team management. All clin-99 ical participants received a confirmed diagnosis of sr-mTBI by a licensed physician as a prerequisite for study inclusion and symp-100 101 tom severity was assessed with the Brain Injury Screening Tool (BIST) <sup>70</sup> upon presentation to Axis clinics or electronically after re-102 cruitment. Healthy controls were recruited through print and social media advertisements, and word-of-mouth. A history of significant medical or neurological conditions unrelated to the scope of this study or contraindication for MRI precluded study partici-103 pation. Additionally, controls were excluded if they: i) had any recent history of mTBI events (< 12 months); ii) were living with any 104 105 long-term effects of previous mTBI, or; iii) had sustained more than 5 lifetime events of mTBI. All participants completed a 1 hour MRI scan and a short demographic questionnaire. All MRI testing was conducted at The Centre for Advanced MRI (CAMRI), Auck-106 land, New Zealand and relevant scans were reviewed for clinically significant findings by a certified radiologist to ensure participant 107 108 safety.

Table 1: Summary of sr-mTBI participant clinical characteristics with reference to healthy controls

ID	Age	DSI	BIST Score	моі	MRI findings
mTBI-01	< 20	5 days	140	Rugby	None
mTBI-02	< 20	5 days	12	Rugby	None
mTBI-03	20s	6 days	78	Rugby	None
mTBI-04	< 20	13 days	18	Rugby	Small fluid signal spaces in R peritrigonal WM - normal. R caudate cleft along ventricular surface - possi- bly developmental or from old ischaemic insult. Not clinically relevant
mTBI-05	< 20	12 days	61	Rugby	None
mTBI-06	20s	13 days	42	Rugby	None
mTBI-07	20s	13 days	13	Football	Minor artifactual T1 signal in pons. Not clinically relevant
mTBI-08	20s	12 days	6	Hockey	None
mTBI-09	20s	6 days	56	Rugby	Minor R orbital fracture (old). Not clinically relevant
mTBI-10	< 20	12 days	54	Rugby	None
mTBI-11	20s	10 days	52	Rugby	None
mTBI-12	30s	13 days	13	Football	None
mTBI-13	< 20	5 days	79	Rugby	None
mTBI-14	20s	13 days	2	Rugby	Small focus of susceptibility in L superior frontal gyrus possibly vascular or nonspecific haemosiderin. Not clinically relevant
mTBI-15	< 20	13 days	22	Rugby	None
mTBI-16	< 20	8 days	117	Futsal	Tiny cleft of fluid signal in R cingulate gyrus - minor developmental anomaly or mature gliosis. Not clini- cally relevant
mTBI-17	20s	13 days	*	Rugby	None
mTBI-18	20s	10 days	34	Gymnastics	None
mTBI-19	20s	13 days	28	Jiu-jitsu	Some artifactual DWI signal in pons. Not clinically relevant
mTBI-20	20s	ll days	69	Surfing	Tiny susceptibility site in R temporal lobe - may be vascular. Not clinically relevant
mTBI-21	< 20	7 days	14	Rugby	Minor susceptibility in transverse sulcus in R mid temporal lobe - nonspecific, may be vascular or reflect haemosiderin deposition from prior small volume haemorrhage. Not clinically relevant
mTBI-22	< 20	13 days	39	Judo	None
mTBI-23	< 20	9 days	34	Rugby	None
mTBI-24	< 20	12 days	68	Rugby	None
mTBI-25	205	12 days	17	Rugby	7mm pineal cyst - normal limits. Some T1 hyperintensity in R cerebellum - artefact compatible. Not clinically relevant
Mean	21.10 (4.43) years	10.4 (3.03) days	44.5 (35.0)/160		No incidental findings. Non-incidental findings not considered clinically relevant
Mean HC	21.10 (4.35) years				No incidental findings. Non-incidental findings not considered clinically relevant

Note. Diagnostic assessment is limited to the volume T1, SWI and DWI sequences with only limited interpretation of the multi-echo T2 stack. Clinical assessments are relevant to identification of micro-haemorrhages, areas of siderosis, T1 appearance, gliosis, volume, ventricular volumes and nonneurological findings. Age is given in a range to prevent re-identification of participants. Possible range of BIST scores are 0 (min) to 160 (max). Clinical group data correspondent to date at MRI only with the exception of the BIST<sup>70</sup> acquired >24 hours post-injury prior to MRI scanning (<14 days post). Abbreviations are as follows: ID = unique identifier; DSI = days since injury; BIST = Brain Injury Screening Tool;<sup>70</sup> MOI = mechanism of injury; MRI = magnetic resonance imaging; L = Left; R = right; \* = missing data.

# 109 Neuroimaging

# 110 Acquisition

- 111 Advanced MRI data were acquired on a 3T Siemens MAGNETOM Vida Fit scanner (Siemens Healthcare, Erlangen, Germany) equipped
- 112 with a 20-channel head coil. A 3D flow-compensated GRE sequence was used to obtain magnitude and phase images for QSM re-
- 113 construction at 1 mm isotropic resolution (TR = 30 ms; TE = 20 ms; FA = 15°; slice thickness = 1.0 mm; FoV = 224 mm; matrix size =
- 114 180 x 224 x 160 mm) for a total acquisition time of ~ 3.43 minutes. For each participant, a high-resolution 3D T1-weighted (T1w)
- anatomical image volume was acquired for coregistration, parcellation and segmentation using a Magnetisation-Prepared Rapid
- 116 Acquisition Gradient Echo (MPRAGE) sequence (TR = 1940.0 ms; TE = 2.49 ms, FA= 9°; slice thickness = 9 mm; FoV = 230 mm; ma-
- trix size = 192 x 512 x 512 mm; GRAPPA = 2; voxel size 0.45 x 0.45 x 0.90 mm) for a total acquisition time of ~ 4.31 minutes. T2
- 118 maps, resting-state functional MRI data, diffusion-weighted images, and susceptibility-weighted images were also acquired as part
- of a larger study and analysed separately. Participant DICOM images were converted to NIfTI files and transformed to brain imaging
- data structure (BIDS)<sup>71</sup> for further processing using *Dcm2Bids*<sup>72</sup> version 3.1.1, which is a wrapper for *dcm2niix*<sup>73</sup> (v1.0.20230411).

# 121 Anatomical image processing

- First, bias field correction was performed on the T1w images for each subject using the N4 algorithm <sup>74</sup> from ANTs.<sup>75</sup> The bias field-
- 123 corrected T1w images were processed in FreeSurfer<sup>76</sup> to 1) delineate pial and grey matter/white matter (GM/WM) boundary meshes,

- and; 2) generate estimates of cortical thickness and curvature for each vertex.<sup>67</sup> Skull-stripping was re-run with additional argu-
- ments, including *-gcut* and adjustments to the watershed threshold as needed, to improve the accuracy of the original FreeSurfer<sup>76</sup> pial surface mesh. The pipeline for T1w and QSM image processing is summarised in Figure 1.

# 127 **QSM processing**

128 QSM images were reconstructed using QSMxT<sup>77</sup> v6.4.2 (https://qsmxt.qithub.io/QSMxT/) available as a container via NeuroDesk<sup>78</sup> (v2024-03-27), a lightweight virtual environment. QSMxT integrates and automates phase unwrapping using a rapid open-source 129 minimum spanning tree algorithm (ROMEO).<sup>79</sup> background field removal with projection onto dipole fields (PDF).<sup>80</sup> and sparsity-130 based rapid two-step dipole inversion (RTS);<sup>81</sup> a pipeline congruent with recent consensus statement recommendations for best-131 practice QSM reconstruction.<sup>82</sup> QSMxT also enables a novel two-pass combination method for hole-filling and artefact reduction.<sup>83</sup> 132 133 which performs parallel QSM masking and reconstruction on susceptibility sources identified as reliable and less reliable. Dual QSM images are then combined into a final integrated image more robust to reconstruction errors and streaking artefacts than those 134 produced using a single-pass approach.<sup>83</sup> A brain mask was also generated using FSL's BET<sup>84</sup> to improve masking and hole-filling 135 of the threshold-based selection algorithm<sup>85</sup> used for two-pass QSM. 136

Subsequent processing was performed locally using FSL.<sup>86–88</sup> For each subject, the raw magnitude image was skull-stripped 137 using FSL's BET<sup>84</sup> with robust brain centre estimation and a fractional intensity threshold of between 0.3 and 0.6. Binary masks 138 139 were derived from the skull-stripped magnitude image and applied to the susceptibility maps to erode non-brain noise around the brain perimeter using fslmaths. Skull-stripped T1-weighted images were used for the linear coregistration of the magnitude im-140 age using FMRIB's Linear Image Registration Tool (FLIRT)<sup>89-91</sup> with 12 degrees of freedom (DoF). Due to variability in acquisition 141 parameters, FoV, and matrix size between subject images, the 12 DoF linear registration provided more accurate alignment com-142 143 pared to the 6 DoF alternative, allowing for better compensation of non-rigid anatomical variations upon visual inspection. The re-144 sulting transformation matrix was used for spatial normalisation of the QSM images to T1w space, effectively upsampling the QSM images. As the analyses are based on cortical depth rather than voxel-wise comparisons, upsampling was not considered a concern. 145 In line with prior research, <sup>67</sup> QSM maps were then thresholded into separate sign (positive and negative) susceptibility maps with 146 fsImaths. Traditional QSM maps represent average voxel-wise susceptibility distributions, <sup>92</sup> thereby obscuring individual suscep-147 tibility sources. Thresholding may enable better distinction of materials with varying biomagnetic properties (e.g., paramagnetic 148 (likely iron) and diamagnetic (likely myelin, calcium, and protein)), and may facilitate a more precise estimation of neurobiological 149 characteristics in analyses. 150

# 151 Cortical column generation

To generate cortical columns and sample signed susceptibility values, we used a pipeline previously applied to DWI data analysis<sup>66</sup> and recently adapted for use with QSM.<sup>67</sup> First, the T1w FreeSurfer<sup>76</sup> recon served as an input into the *easy\_lausanne* tool (https://github.com/r This stripped-down fork of the open-source Connectome Mapper<sup>93</sup> separates the cortex into five atlases, ranging from 34 to 250 ROIs per hemisphere, according to the Lausanne multi-scale atlas.<sup>94</sup> For subsequent analyses, we focused on the atlas with 34 ROIs per hemisphere, which is equivalent to the Desikan-Killiany atlas<sup>95</sup> native to FreeSurfer.<sup>76</sup>

Cortical columns were created for each hemisphere in T1w space with write\_mrtrix\_tracks<sup>96</sup> in MATLAB (version R2024a), 157 which was used to connect vertex pairs between the pial and GM/WM boundary surface meshes. Each cortical column was seg-158 mented into 21 equidistant depths, each with a step size of 5% of the cortical thickness, <sup>65,69</sup> from the pial surface to the GM/WM 159 boundary using MRtrix3 tckresample.<sup>96</sup> Here, the step-wise depths represent the 21 equidistant segmentations rather than spe-160 cific cellular laminae (L1 to L6) of the cortex. It is important to distinguish results produced using this approach from ultra-high field 161 investigations of cyto- and myelo-architecture in the cerebral cortex; results described herein are related to cortical depth, rather 162 than *layer.* The columns were categorised based on cortical curvature, derived from FreeSurfers <sup>76</sup> Gaussian curvature values at 163 each GM/WM boundary vertex<sup>97</sup> and guantified in units of 1/mm<sup>2</sup>. The categories included the gyral crown (curvature values: 0.6 164 to 0.1), sulcal bank (0.1 to 0.1), and sulcal fundus (0.1 to 0.6).<sup>67</sup> Positive curvature values indicated sulci, while negative values indi-165 cated gyri, with higher values corresponding to deeper curvatures.<sup>67</sup> Only columns ranging from 0.5 mm to 6 mm in length were 166 included in the analysis to capture plausible cortical morphology.<sup>98</sup> Depth was measured in percentage of cortical thickness rather 167

168 than absolute metrics (mm) to mitigate any variability between control and clinical participants.

#### Figure 1: Image processing pipeline

Steps are performed independently and in parallel for each participant. Quantitative susceptibility maps were reconstructed from magnitude and phase images using QSMxT, and eroded by the skull-stripped, binarised magnitude image mask to remove non-brain sources of susceptibility. QSM images were then aligned to T1-weighted images, and thresholded into positive and negative susceptibility maps. FreeSurfer recon was used on bias field-corrected T1-weighted images to produce pial and GM/WM boundary surface meshes, and vertex pairs were then joined to create cortical columns. Parcellations of the cortical grey matter were estimated by feeding the T1w FreeSurfer recon into *easy\_lausanne*. Columns were then assigned specific ROIs and curvature bins, and used to sample susceptibility from thresholded QSM maps.

# 169 Statistical analyses

- 170 To provide a detailed analysis of microstructural differences associated with sr-mTBI while maintaining result granularity, we per-
- 171 formed analyses at the bilateral regional level using MATLAB (2024a). Average positive and negative susceptibility values were ex-
- 172 tracted from 21 cortical depths for all 34 ROIs. Each ROI was analysed by independent curvature bin (gyral crown, sulcal bank, and
- 173 sulcal fundus) as well as combined curvature as a whole-ROI measure. To control for multiple comparisons and align with prior re-
- search, <sup>67</sup> we applied a false discovery rate (FDR) correction <sup>99</sup> to the p-values for 21 comparisons (one for each depth) for each ROI/curvature
- profile. Due to precise age-matching of participants, age was not considered a covariate or confounding variable of interest for between-
- 176 group comparisons. However, to explore the relationship between QSM values and age in the entire sample, partial Pearson correla-
- 177 tion coefficients were calculated between age and both positive and negative susceptibility values independently for all 34 curvature-
- 178 combined ROIs, at each depth, whilst controlling for group effects. To explore the relationship between susceptibility values and
- other sr-mTBI-related variables, Pearson correlation coefficients were also calculated between Brain Injury Screening Tool (BIST) 70
- 180 scores and injury latency (days since injury (DSI)) and both positive and negative susceptibility values independently for the the sr-
- 181 mTBI sample only. mTBI-17 was excluded from correlations between BIST and both susceptibility signs due to missing data. Corre-
- 182 lations were also corrected for 21 depth-wise comparisons using FDR procedures.<sup>99</sup> Given the limited sample size and the need to
- 183 conserve degrees of freedom in this exploratory study, regression analyses were deliberately omitted.

# 184 **RESULTS**

# 185 Regional depth- and curvature-based analyses

- 186 Using independent sample t-tests, we examined depth- and curvature-specific between group differences in bilateral regional sus-
- 187 ceptibility (positive and negative) for each of the 34 ROIs (see Figure 2). P-values were corrected for 21 cortical depths for each ROI/curvature
- 188 combination using FDR procedures.<sup>99</sup>

# **Bilateral Regional Comparisons**

# A. Positive susceptibility

# B. Negative susceptibility

#### Figure 2: Bilateral regional curvature and depth results.

Colour maps demonstrate differences in magnetic susceptibility at each cortical depth (where 0% depth is proximal to the pial surface and increases toward the GM/WM boundary at 100% depth), separately for each curvature bin (crown, bank, fundus) as well as combined curvature as a whole-ROI measure. Independent sample t-tests examined group differences in susceptibility at each depth, for each curvature, at each ROI. P-values were corrected for multiple comparisons across 21 cortical depths using FDR. A. Positive susceptibility values were significantly more positive for participants with sr-mTBI than healthy controls in temporal ROIs and significantly less positive in frontal regions only. B. Susceptibility values were significantly less negative for sr-mTBI participants than controls in temporal ROIs and significantly more negative in parietal ROIs. OFC = orbitofrontal cortex; mPFC = middle prefrontal cortex; STS = superior temporal sulcus; LOC = lateral occipital cortex; ACC = anterior cingulate cortex. Figure based on Merenstein et al. (2024). Depth- and curvature-based quantitative susceptibility mapping analyses of cortical iron in Alzheimers disease. *Cerebral Cortex*.

# 189 Positive susceptibility

- 190 Across bilateral depth profiles, participants with sr-mTBI exhibited significantly higher positive susceptibility than controls in the
- 191 temporal lobe only (see Figure 2A), specifically in superficial depths of the sulcal bank and fundus of the parahippocampal gyrus, a
- 192 finding that was conserved when curvature was combined as a whole-ROI measure (see also Figure 3.1A and Figure 3.2A). Suscep-
- 193 tibility was decreased following sr-mTBI in the superficial gyral crown of the rostral medial prefrontal cortex (mPFC) and superficially
- in the frontal pole when curvature was combined. No significant differences between groups were found in bilateral susceptibility
- 195 values in parietal, occipital, or insular lobes.

# 196 Negative susceptibility

Across bilateral depth profiles, participants with sr-mTBI exhibited significantly less negative susceptibility than controls in the temporal lobe only (see Figure 2B). This finding was focal to the superficial depths of the fundus in the parahippocampal gyrus, as well as when curvature was combined (see also Figure 3.1B and Figure 3.2B). Negative susceptibility was more negative for participants with sr-mTBI deep in the supramarginal gyral crown of the parietal cortex only. No significant differences between groups for curvature were found in the sulcal bank (see Figure 3B). No significant differences were found in bilateral frontal, occipital, or insular lobes.

# 1. Significant Region-wise Susceptibility

### A. Positive susceptibility

# B. Negative susceptibility

### B. Negative susceptibility

### 2. Significant ROIs - Combined Curvature

# Figure 3: Significant region-wise susceptibility values.

1. Differences in susceptibility values between mTBI participants and controls for significant regions of interest only. A. Positive susceptibility values were significantly higher for participants with mTBI than healthy controls in superficial depths of the sulcal bank and fundus of the parahippocampal gyrus, as well as when curvature was combined. Values were significantly less positive for mTBI participants superficial frontal pole when curvature was combined. B. Susceptibility values were significantly less positive for mTBI participants superficial frontal pole when curvature was combined. B. Susceptibility values were significantly less positive for mTBI participants than controls in the superficial depths of sulcal fundus in the parahippocampal gyrus, as well as when curvature was combined. Values were significantly more negative after mTBI deep in the supramarginal gyral crown. Susceptibility is measured in parts per million (ppm). mPFC = middle prefrontal cortex. 2. Medial visualisation of significant ROIs after mTBI for both positive (A) and negative (B) susceptibility maps when curvature was combined as a whole-ROI measure. Surface lines demarcate borders between ROIs, projected onto an inflated surface. Significant ROIs are filled; intensity values relate directly to pFDR significance level. For visualisation purposes, depth was reduced from 21 to 7 by averaging pFDR values every 3 consecutive depths where 0% is proximal to the pial surface and 100% to the GM/WM interface.

# 203 Bilateral regional correlations

We used partial Pearson correlation coefficients to examine the relationship between age and regional depth-wise susceptibility (positive and negative) for combined curvature at each ROI across the entire sample, whilst controlling for group status. Additionally, we explored the correlation between susceptibility values and 1) BIST scores<sup>70</sup> as an indicator of injury severity, and; 2) DSI at the time of the MRI scan as a marker of injury latency, in the mTBI sample only (see Figure 4). Negative susceptibility was transformed to absolute values to better represent relationships between variables (see Figure 4B). P-values were adjusted for 21 cortical depths within each ROI using FDR methods.<sup>99</sup>

# A. Positive Susceptibility Correlations

# Figure 4: Correlations between positive or negative susceptibility and variables of interest

i: The relationship between age and positive (A) and negative (B) susceptibility values was assessed for each depth for combined curvature as a whole-ROI measure using partial correlations to control for the effects of group status. ii: the relationship between BIST scores as a marker for injury severity and susceptibility sign values was explored, along with; iii: the relationship between susceptibility sign values and DSI at the time of MRI scan as a marker of injury latency. Negative (B) susceptibility was transformed into absolute values to better represent the relationship between variables. BIST = Brain Injury Screening Tool; DSI = days since injury (at time of MRI scan).

# 210 Age

#### 211 Positive susceptibility

We observed significant positive correlations between age and iron-related positive susceptibility distributions exclusively at deeper 212 213 cortical depths near the GM/WM interface (see Figure 4A(i)). In the frontal cortex, regions with statistically significant age-related increases in positive susceptibility values included the pars orbitalis, pars triangularis, superior frontal gyrus, paracentral lobule, and 214 215 precentral gyrus. In the parietal cortex, significant regions were the superior and inferior parietal lobules, supramarginal gyrus, and 216 precuneus. In the temporal lobe, significant positive correlations were found in the parahippocampal gyrus and inferior temporal 217 gyrus. The only cingulate region to exhibit a positive age-related correlation was the isthmus. No significant positive correlations 218 with age were identified in any ROIs within the occipital cortex. Conversely, we identified significant negative correlations between age and positive susceptibility exclusively at superficial cortical depths near the pial surface, demonstrating an inverse pattern to 219 the positive correlations. In the frontal cortex, the areas showing significant negative correlations were the pars orbitalis, pars trian-220 gularis, superior frontal gyrus, paracentral lobule, and precentral gyrus. In the parietal cortex, the postcentral region exhibited signif-221 icant negative correlations. No significant negative correlations between positive susceptibility and age were apparent in temporal, 222 223 occipital, or insular ROIs.

# 224 Negative susceptibility

Significant positive relationships were observed between absolute negative susceptibility values and age, primarily in the superficial 225 depths of ROIs across all lobes, which at times extended to the GM/WM border (see Figure 4B(i)). In the frontal lobe, ROIs exhibiting 226 227 significant positive correlations between age and negative susceptibility included the frontal pole, rostral mPFC, caudal mPFC, pars opercularis, superior frontal gyrus, and precentral gyrus. All examined ROIs in the parietal cortex exhibited significant positive rela-228 tionships, namely, in the superior parietal lobule, inferior parietal lobule, postcentral gyrus, supramarginal gyrus, and precuneus. In 229 the temporal cortex, significant positive correlations were found in the middle temporal gyrus and temporal pole. All occipital ROIs 230 231 showed significant positive correlations, including the LOC, pericalcarine cortex, lingual gyrus, and cuneus. Within the insular cortex, only negative susceptibilities in the insula demonstrated a significant positive relationship with age. In contrast, significant negative 232 correlations with age were observed only in the deeper cortical layers closer to the GM/WM junction of parietal regions, specifically 233 in the superior parietal lobule and precuneus. 234

# 235 Injury severity

We observed significant positive correlations between BIST scores and positive susceptibility values in the mid-depths of the frontal pole and in superficial depths of the bank of the superior temporal sulcus (STS) (see Figure 4A(ii)). No significant correlations were observed between negative susceptibility and BIST scores (see Figure 4B(ii)).

#### 239 Injury latency

No significant correlations between DSI at time of MRI and positive susceptibility values were observed for any ROI (see Figure 4A(iii)). Negative susceptibility and DSI were positively correlated in superficial depths of the bilateral paracentral gyrus in the frontal cortex only (see Figure 4B(iii)).

# 243 **DISCUSSION**

Previous research seeking to understand the role of brain iron following mTBI has focused primarily on susceptibility distributions in subcortical or global grey matter and/or white matter, neglecting the vulnerability of cortical regions to microstructural damage following an mTBI. The one investigation inclusive of cortical ROIs was constrained by macroscopic voxel-wise techniques, which lack the anatomical precision necessary to detect depth- or curvature-specific differences in magnetic susceptibility. To address this gap in the literature, we adapted a new analytic technique already demonstrating efficacy in Alzheimer's disease research to perform the first investigation of sr-mTBI-related differences in magnetic susceptibility as a function of cortical depth and curvature. In line with contemporary approaches in QSM research, we separated positive (iron-related) from negative (myelin-, calcium-, and protein-

related) sources of susceptibility to enable more accurate estimation of underlying biological substrates.

252 Our findings revealed increased positive susceptibility exclusive to the temporal lobe, specifically in the superficial depths at

sulcal curvatures in the bilateral parahippocampal gyrus. This pattern was conserved when curvature was aggregated as a whole-253 ROI measure. In contrast, age-related positive susceptibility indicative of iron deposition was observed at deep cortical depths, closer 254 to the interface with the white matter, in the overall sample. These findings suggest that increases in positive susceptibility close to 255 the cortical surface indicate abnormal, injury-related iron accumulation after mTBI. Results corresponded with analyses of nega-256 tive susceptibility, which demonstrated less diamagnetism in the superficial depths of the sulcal parahippocampal gyrus after mild 257 brain trauma. In addition, negative susceptibility was positively correlated with age in superficial depths only, suggesting an align-258 ment with age-related calcification processes in superficial cortical layers that is well supported by the literature; a pattern oppo-259 site to mTBI-related negative susceptibility effects. Fewer correlations were found between subjective injury status or time elapsed 260 261 since injury and susceptibility, supporting a body of research demonstrating little relationship between objective injury measures and subjective self-report. 262

# 263 **Depth**

- In-vitro histological studies have demonstrated variations in iron distribution relative to specific cortical laminae (e.g., Perls iron stain-264 ing), where concentrations are lowest at the pial surface and increase progressively through GM toward its junction with WM.<sup>100</sup> 265 These findings have been corroborated by iron-sensitive  $R_2^*$  mapping of ex-vivo tissue samples using ultra-high field (7T) MRI,<sup>100</sup> 266 which also exhibit high congruence with in-vivo QSM.<sup>101</sup> Taken together, these studies suggest that iron density in the cortex re-267 flects distinct cyto- and myelo-architecture, with variance between layers. In healthy populations, iron density should be sparse at 268 the pial surface and increase with depth. Conversely, our findings indicate an abnormal distribution pattern of positive susceptibility 269 related to iron deposition exclusively in superficial depths of the parahippocampal gyrus in temporal cortex following injury (see Fig-270 ure 2A, Figure 3.1A and Figure 3.2A). This increased positive susceptibility at the acute stage of mTBI is directly inverted for depth 271 comparative to healthy laver-specific variation <sup>100,101</sup> and patterns related to normal ageing in this range of the lifespan (see Fig-272
- 273 ure 4A(i)), suggesting an injury-specific model of cortical microstructural trauma (see Figure 5).

# Iron Distribution in the Parahippocampal Gyrus

# Figure 5: Iron and positive susceptibility distributions in the parahippocampal gyrus.

Visualisation of depth-specific positive (iron-related) susceptibility distributions. (A) Depicts increased positive susceptibility following mTBI relative to healthy controls restricted to superficial depths of the parahippocampal gyrus. This pattern does not overlap with (B) validated patterns of lower iron concentration proximal to the pial surface, and increasing towards the GM/WM interface as a pattern of normal layer-specific distributions, or; (C) normal age-related increases in positive susceptibility in this population (16-32 years) restricted to the deeper cortical depths closer to the GM/WM boundary. Depiction of the hippocampal formation inspired by illustration in Ranson & Clark (1959). *The anatomy of the nervous system: Its development and function* (10th ed.). W. B. Saunders Co.

The focal nature of increased positive susceptibility in superficial depths suggests iron accumulation near small blood ves-274 sels.<sup>11</sup> Concordantly, microhemorrhage and aggregation of activated microglia around perivascular sites are well documented af-275 ter mTBI,<sup>25,102,103</sup> Here, it is tempting to speculate about potential mechanisms of iron overload following mTBI. Non-heme iron 276 277 (i.e., bound to proteins such as ferritin and transferrin) generally enters the brain through active transport across the blood-brainbarrier (BBB) via vascular endothelial cells; a constant process that is closely regulated within the central nervous system to ensure 278 homeostasis.<sup>26</sup> Injury-induced acute cerebral microvascular dysfunction and increased permeability of the BBB,<sup>104,105</sup> likely in-279 creases iron transport into these superficial cortical layers<sup>22,106</sup> which could result in a perivascular accumulation of iron. Notably, 280 redox reactions involving non-heme iron are a significant source of reactive oxygen species (ROS);<sup>25</sup> when labile iron accumulates 281 282 to pathological levels, it can exceed the capacity of storage proteins inducing oxidative stress, protein and DNA damage, and ferroptosis.<sup>22,25,107</sup> This labile iron is frequently considered a critical contributor to secondary injury mechanisms<sup>25,26,102</sup> and represents 283 the primary source of paramagnetic susceptibility in the brain on QSM.<sup>108</sup> As such, iron accumulation acting as a catalyst for auto-284 toxic circuits<sup>106</sup> is a candidate hypothesis by which iron dyshomeostasis after mTBI could account for the increased magnetic sus-285 ceptibility of these compromised perivascular regions on QSM. Iron overload may represent a promising early marker of acute cell 286 287 damage and mTBI-related neuropathology as well as degeneration of neural tissue downstream. However, as the precise mechanisms by which iron is released in the brain are still under investigation,<sup>26,29</sup> these mechanisms cannot yet be disambiguated. 288

Whilst the relationship between positive susceptibility and iron is well established, the mechanisms underlying diamag-289 netic sources of contrast are less well understood and more challenging to elucidate.<sup>67,68,109</sup> Recent research indicates that the 290 primary source of diamagnetic contrast is myelin, <sup>110</sup> but contributions are also made by calcium <sup>33–35</sup> and the deposition of pro-291 teins such as amyloid-beta (A $\beta$ ).<sup>36,37</sup> Our results suggest that negative susceptibility is decreased in the parahippocampal gyrus at 292 superficial depths following mTBI. Myeloarchitecture studies indicate that Layer I of cerebral cortex consists primarily of axons, den-293 drites, and axon terminals, the cell bodies of which are located in deeper layers.<sup>111</sup> Although the cerebral cortex is not well known 294 for high myelin content.<sup>68</sup> decreased positive susceptibility at these superficial depths could indicate changes to surface axons. 295 This pattern coincided with increased positive susceptibility in the superficial parahippocampal gyrus, suggesting a dual model 296 of perivascular microstructural trauma focal to this region. The majority of iron present in the human brain parenchyma is stored 297 as non-heme iron within myelin-maintaining oligodendroglia and in myelin itself;<sup>112</sup> pathological iron levels have been known to 298 damage both. 113-115 Mechanisms leading to co-localisation of increased positive susceptibility and decreased negative suscepti-299 bility observed in this study are further supported by research into pathogenesis of multiple sclerosis, which indicates that neuroin-300 flammation and altered BBB permeability can result in iron accumulation in macrophages and other iron-related cytotoxic events, 301 such as oxidative stress, causing degradation of oligodendrocytes and axons, <sup>22,113,115</sup> Conversely, increased negative susceptibil-302 ity was mostly observed at deeper cortical depths closer to the GM/WM junction, which might reflect aggregation of A $\beta$  inherent 303 to AD, <sup>116</sup> and sometimes present in CTE, <sup>12</sup> or calcifications known to negatively affect cognition. <sup>117</sup> Notably, the injury-related ac-304 cumulation patterns did not overlap with age-related changes in negative susceptibility, which increased at superficial depths (see 305 Figure 4B(i)). This suggests that both decreased negative susceptibility in superficial depths and increased negative susceptibility at 306 deeper cortical depths may result from abnormal, injury-related, neuropathological processes. 307

### 308 Curvature and ROI

309 Prior research has noted that the sulcal fundus is particularly vulnerable to injury in mTBI due to increased susceptibility to mechanical deformation 12,64 and the 'water hammer effect.' 63 The current study supports a fundus-specific model of damage in mTBI; 310 the only persistent differences between groups in both positive and negative susceptibility were observed in sulcal regions of the 311 bilateral parahippocampal gyrus (positive susceptibility: sulcal bank and fundus; negative susceptibility: sulcal fundus (see Figure 2 312 and Figure 3)). The focal nature of injury to these concave regions extends prior work noting increased mean cortical curvature in 313 the sulcus<sup>118</sup> and sulcal widening<sup>63</sup> after mTBI. Results are also consistent with observations of mTBI-related vascular injury and 314 microhemorrhage in the sulcal fundus on SWI.<sup>63</sup> Additionally, the medial temporal lobe is a notable site of injury in sr-mTBI and 315 previous research has highlighted the associations between sr-mTBI and loss of cortical thickness in the parahippocampal gyrus 316 along with reductions in parahippocampal volume.<sup>119</sup> Contextually, the parahippocampal cortex acts as a hub region in a network 317

connecting areas of the frontal, parietal, and temporal lobes <sup>120</sup> and represents a vital link between the default-mode network and the medial temporal lobe memory system, as evidenced by resting-state fMRI studies. <sup>121</sup> As such, it is integral to various cognitive processes including visuospatial processing and episodic memory <sup>122</sup> and the facilitation of contextual associations fundamental to higher order cognitive performance. <sup>120</sup> The co-localisation of iron-related deposition and potential myelin changes, particularly in integrative superficial regions, within the temporal parahippocampal gyrus is consistent with the memory impairments symp-

# 323 tomatic of sr-mTBI.<sup>103</sup>

# 324 Age and clinical correlates

Increasing iron in deep grey matter nuclei and some regions of the cortex is a hallmark of normal ageing.<sup>29,60</sup> Research indicates 325 that age-related iron increases occur primarily in the motor and premotor cortices, as well as the superior prefrontal and parietal 326 cortices. <sup>60,123</sup> Additionally, these increases have been reported in the insula<sup>123</sup> and hippocampus.<sup>124</sup> Histological evidence sug-327 gests that normal increases in cortical non-heme iron may be especially pronounced in younger individuals, sharply increasing dur-328 ing childhood and plateauing at around 30 years of age, depending on region.<sup>60,125</sup> These observations are supported by some <sup>123,126</sup> 329 but not other <sup>127</sup> cross-sectional iron-sensitive MRI findings in adjacent age groups. Our findings support age-related cortical iron 330 increases in a youthful population. In line with prior research, ROIs with age-related increases in likely iron content were most dense 331 in frontal and parietal lobes, in addition to two loci in the temporal lobe and one in the insular cortex (see Figure 4A(i)). Of all cor-332 tical regions, the motor system is particularly affected by age-related iron deposition, <sup>123</sup> a pattern mirrored in our findings which 333 show a notable density in the primary motor cortex. Our results suggest that age-related increases are restricted to deeper corti-334 cal depths closer to the GM/WM junction, which are known to naturally express higher iron levels in the healthy population.<sup>100,101</sup> 335 These deeper layers contain large pyramidal cells.<sup>111</sup> which could speculatively accumulate iron differently. Indeed, previous re-336 search <sup>67</sup> has suggested that because age is more predictive of delayed response time rather than difficulties in decision-making.<sup>128-130</sup> 337 age-related iron accumulation should show a preference for deeper layers responsible for output, rather than more integrative su-338 perficial regions.<sup>131</sup> In addition, we observed age-related increases in negative magnetic susceptibility exclusively close to the pial 339 surface. Previous studies utilising negative QSM have shown similar distributions at superficial depths.<sup>68</sup> This pattern is well-supported 340 in the literature, as research indicates that calcifications commonly occur in areas with high vascularization and metabolic activ-341 ity, <sup>33</sup> such as the cortical surface. Taken together, our findings indicate that age-related increases in iron are likely restricted to deep 342 cortical depths, while diamagnetic calcifications are likely to occur at superficial depths. Both observations are supported by strong 343 biological plausibility and well-documented scientific evidence. This reinforces the conclusion that observed differences in both 344 positive and negative susceptibility following sr-mTBI reflect pathological processes distinct from those associated with normal 345 ageing. 346

The general lack of correlation between positive or negative susceptibilities and BIST scores may be attributed to the underreporting of symptoms notorious in sr-mTBI, <sup>132</sup> which would preclude accurate correlations. Whilst iron negatively correlates with cognitive symptoms in mTBI, <sup>133</sup> it is well-documented that subjective assessments of injury severity do not reliably reflect objective brain injury or recovery status<sup>20</sup> and cognitive/clinical symptoms do not align with neuroimaging findings.<sup>21</sup> Additionally, the lack of correlation between positive or negative susceptibilities and injury latency suggests that acute neuropathology may persist into the subacute and chronic stages, necessitating further research to elucidate the time course of secondary injury in sr-mTBI.

# 353 Implications

The role of iron in acute responses following cytotrauma, as well as its co-localisation with, and involvement in, misfolded proteins in neurodegenerative diseases, including CTE, identifies it as a potential marker of early degenerative processes.<sup>29,30</sup> Interestingly, the temporal lobe and hippocampus are primary loci of atrophy and tau deposition in CTE, <sup>12,134</sup> and iron has been found in neurofibrillary tangles within these regions.<sup>30</sup> In CTE, these neurofibrillary tangles favour superficial cortical layers (II/III) <sup>135,136</sup> and aggregate around small blood vessels, <sup>137</sup> especially at the sulcal fundus.<sup>64</sup> This laminar predilection is not seen in other tauopathies, like AD, where tau phosphorylation generally occurs in deeper layers (V/VI).<sup>138</sup> Indeed, this specific distribution is considered pathognomonic of CTE.<sup>12,137</sup> Notwithstanding the short-term effects of iron overload, which have been linked to secondary injury in mTBI.<sup>25,102</sup>

the association between iron-mediated oxidative stress and hyperphosphorylation of tau<sup>27</sup> coupled with the similarity of iron distributions observed in this study to hallmark distributions of tauopathy and degeneration in CTE raises important questions about the disease path from acute injury to eventual tissue degeneration. The precise mechanisms underlying CTE remain an active area of research, but these findings suggest that iron may serve as a candidate biomarker, warranting further investigation. Until such a time, any parallels drawn between the pattern of iron distribution in this study and the hallmark features of CTE tauopathy can, at this stage, only be speculative.

Here, follow-up investigations will be of paramount importance. A better understanding of iron and other neurobiological 367 correlates, such as myelin damage or protein aggregation, may be essential for developing effective care and targeted treatments 368 at the acute stage of mTBI, which could protect against adverse consequences later in life. Recent research has explored the possi-369 bility of using heavy metal chelation as a therapeutic target for iron in AD<sup>139</sup> and TBI.<sup>31</sup> In AD, this approach has had limited suc-370 cess, perhaps due to the accumulation of iron over a long time course; once iron overload becomes apparent, cell death has already 371 372 occurred.<sup>106</sup> However, mechanisms of acute injury-related iron overload may be distinct from long-term aggregation. Murine models using iron chelators such as Deferoxamine <sup>140-143</sup> and *N*,*N*'-Di(2-hydroxybenzyl)ethylenediamine-*N*,*N*'-diacetic acid monohy-373 drochloride (HBED)<sup>144</sup> have shown promise in reducing TBI symptomatology, likely through inhibition of ferroptosis and reduc-374 tions in neuroinflammation, ROS, and gliosis. More research is needed to understand efficacy in humans, but this remains a possi-375 ble avenue for limiting the effects of acute iron dyshomeostasis which may contribute to degenerative effects evident in later life. 376

# 377 Limitations and future research

While QSM offers valuable insights into iron content and distribution, at lower field strengths (i.e., 3T) voxel resolution is restricted 378 and does not reflect specific architectonics of cortical tissue. Cortical column analyses were thus constrained to investigations of 379 depth rather than susceptibility distribution specific to cortical laminae. Future research could benefit from applying cortical col-380 381 umn analysis to images with higher resolutions, for example those collected on high field scanners, or by pushing images to sub-1mm resolutions insofar as signal-to-noise ratios are not compromised. The present study utilised a single-echo QSM sequence, 382 limiting thresholding of susceptibility sources to between voxels. To enable thresholding within voxels, future studies should incor-383 porate multi-echo sequences<sup>101,145,146</sup> where available, thereby enhancing the biological interpretation of the findings. Incorpo-384 rating complementary modalities, such as positron emission tomography (PET), would provide a more comprehensive understand-385 ing of cellular metabolism and neurobiological processes, potentially linking these to the observed mTBI-related differences and 386 enabling more biologically informed inferences. Inclusion of protein assays, such as blood-based biomarkers, would also aid in cre-387 ating a more comprehensive picture of the biological consequences of sr-mTBI. A range of potential confounds were not controlled 388 389 for in this study including prior injuries, genetic predispositions, and environmental influences, which may affect injury severity and 390 presentation,<sup>?</sup> and future research should consider including additional measures to control for these variables. Given that this study was conducted exclusively in a male cohort, the generalisability of the findings to females may be limited. Sex differences in 391 injury effects are reportedly influenced by a range of factors, including hormonal variations, <sup>147</sup> the use of oral contraceptives, <sup>148</sup> 392 and differences in neck musculature.<sup>149</sup> Future research should extend investigations to female athletes and consider compar-393 isons by sex. Finally, given the limitations of inferring long-term consequences of sr-mTBI from data collected at the acute stage, 394 395 future research should prioritise longitudinal studies tracking athletes over time. This prospective approach would yield more precise information compared to retrospective studies, providing valuable insights into the relationships between the number of mT-396 397 Bls sustained, iron accumulation, recovery trajectories, and long-term outcomes. In lieu of longitudinal research, planned upcoming studies will utilise comparison of individual z-scores relative to healthy population norms to better clarify the prevalence of adverse 398 399 outcomes following sr-mTBI. This approach will aim to enhance our understanding of the impact of sr-mTBI at the individual level, which may be obscured by group-level analyses. 150,151 400

# 401 CONCLUSIONS

To better characterise the mechanisms of mild traumatic brain injury at the acute stage, we conducted the first QSM study to assess depth- and curvature-specific regional patterns of positive (iron-related) and negative (myelin-, calcium-, and protein-related) mag-

- 404 netic susceptibility in the cerebral cortex following injury. We observed co-localisation of increased positive susceptibility with de-
- 405 creased negative susceptibility in the parahippocampal gyrus, indicating a possible accumulation of iron concomitant with myelin
- 406 changes after injury. This distribution pattern was observed in the superficial depths of the sulcus, suggesting perivascular trauma
- 407 due to mechanical forces. The pattern appeared distinct from age-related differences in positive and negative susceptibility and
- 408 was reminiscent of pathognomonic patterns of tau pathology in CTE, which is known to co-localise with iron. These results support
- 409 a complex, dual-pathology model of trauma after mild head injury and have implications for understanding microstructural brain
- 410 tissue damage following mTBI.
