Supplemental Figure 1: Cell sorting and QC.

A.

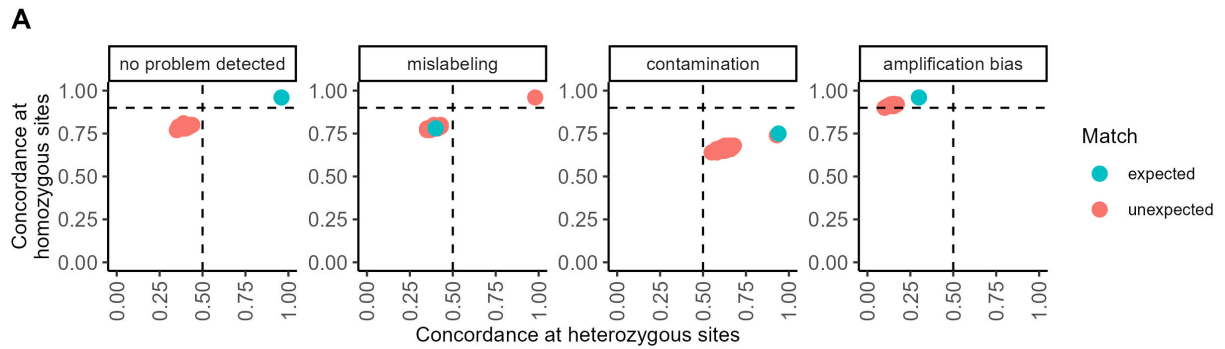

B.

(A) Granulocytes magnetic cell sorting from EDTA-anticoagulated peripheral whole blood. Blood was processed for granulocytes negative cell sorting within 30 minutes after collection. ¼ and ½ of the sorted granulocytes were further

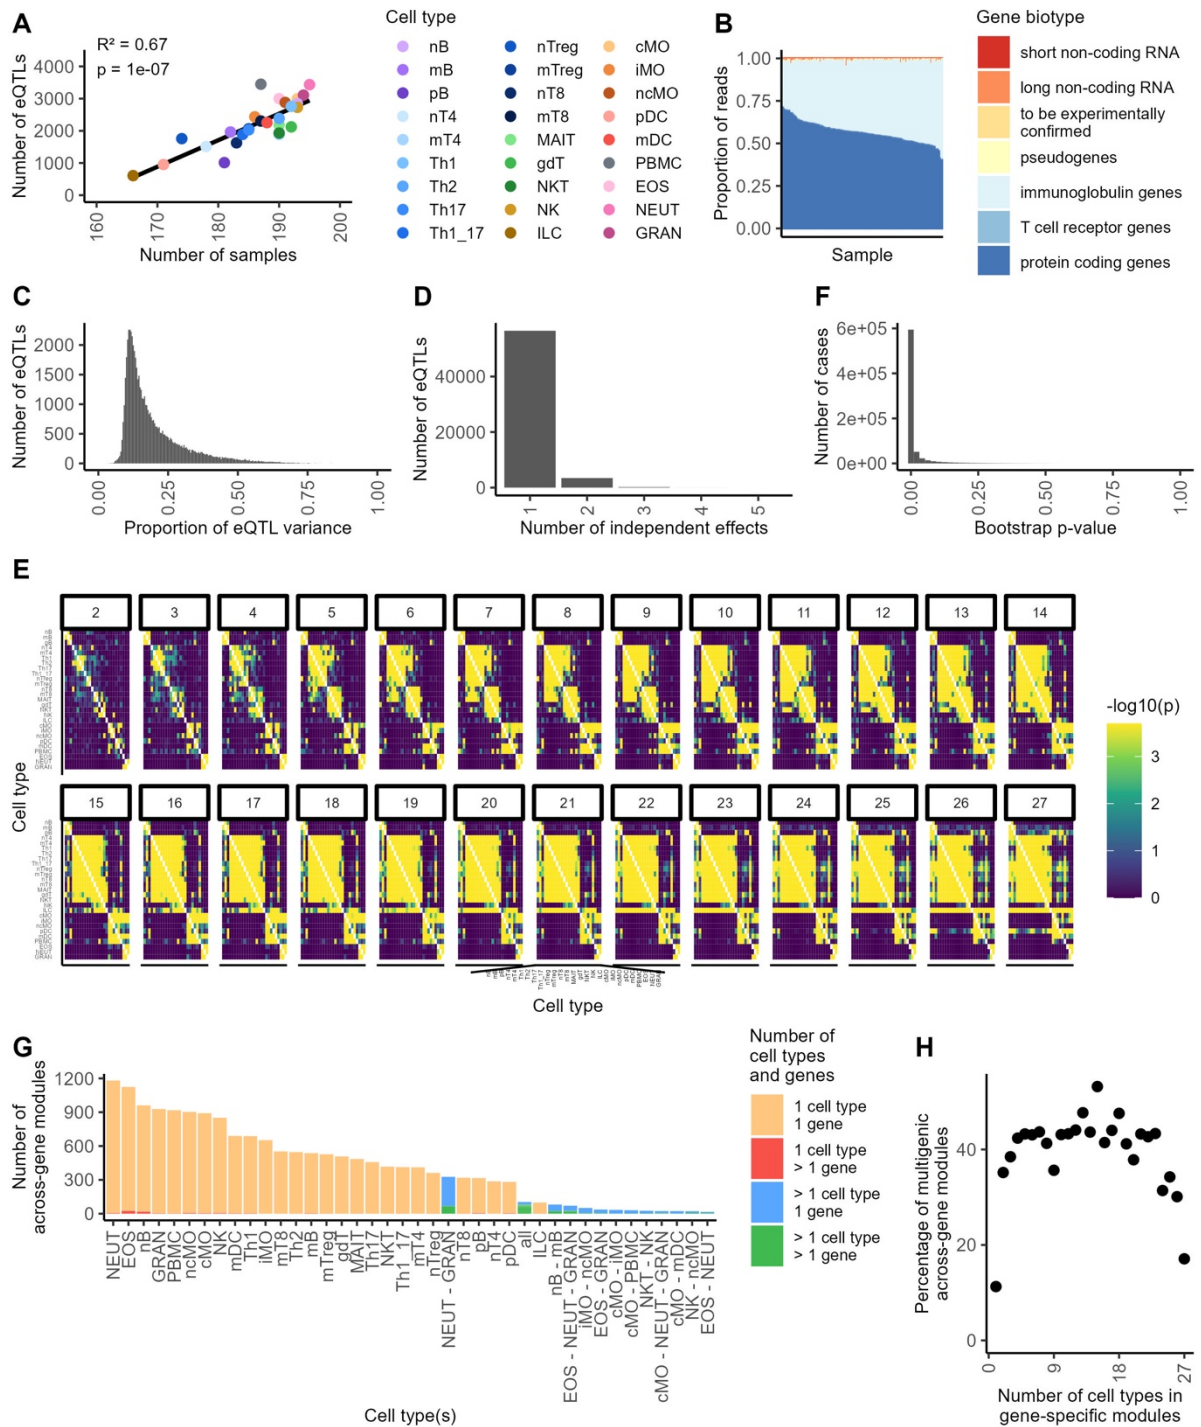

processed separately and respectively for Neutrophils and Eosinophils selection. The remaining  $\frac{1}{4}$  was immediately frozen until use. For QC of the cell sorting, an aliquot before and after each sorted fraction were stained using anti-CD15 and anti-Siglec-8 antibodies, together with viability dye. Left panel shows the percentage of each sorted population before and after sorting. **(B)** Flow cytometry cell sorting and QC of PBMC derived cell populations. Representative FACS plots illustrating gating strategies and QC after cell sorting for B cells (upper right panel), MAITs, gd T and ILC cells (middle left panel), monocytes and dendritic cells (middle right panel), NK and NKT cells (lower left panel), and conventional CD8 and CD4 T cells (lower right panel). For a detailed description of subset names, see STable 2. For information on the flow-cytometry antibodies used in this study, see STable 29. Red quadrants indicate the target sorted cell types.

**Supplemental Figure 2: Quality control of the bulk RNA-Seq data on 27 circulating immune cell populations.**

**(A)** Examples of issues detected by confronting genome and transcriptome genotypes. From left to right: (i) Example of an RNA sample that matches its presumed donor (green dot); the red dots correspond to the confrontation of that RNA sample with the DNA of all other individuals. (ii) Example of an RNA sample that matches the DNA of an individual that is not the presumed donor. (iii) Example of an RNA sample that is likely contaminated (mixture between two samples), as it is “too heterozygous” and hence shows a drop in concordance at homozygous genotypes for both the presumed donor (green dot) and the contaminating individual (co-positioned red dot). (iv) Example of a likely PCR issue; the RNA appears “too homozygous” and hence shows a drop in concordance at heterozygous genotypes. **(B)** Example of issues detected when confronting presumed cell type vs inferred transcriptome-based cell type: tSNA map of 2,444 samples from 13 cell types labeled by presumed cell type of origin before (left) and after (right) quality control. Based on the expression level of 500 most variable genes. **(C)** Hierarchical tree for 24 of the 27 cell types (PBMC, granulocytes and memory CD4 were not included because being mixtures of cell types) obtained from  $1 - |\text{Spearman's correlation}|$  between the mean (across all samples) expression levels of the 4,000 most variable (ANOVA F value of cell type effect) coding genes using “average” method. The numbers on the nodes correspond to the proportion of trees recapitulating the same split when varying the number of variable genes considered from 250 to 8,000 (32 analyses) and using the same method. The tree shown is the best supported tree in the method. Nearly identical (most supported) trees were obtained when applying the “ward.d” and “ward.d2” methods. The blue line marks the only differences that was observed with the “ward.d2” method.

### Supplemental Figure 3: eQTL mapping and construction of regulatory modules in 27 circulating blood cell populations.

**(A)** Number of detected eQTL as a function of the number of usable samples for the corresponding (color labeled) cell type. **(B)** Demonstration of the inter-individual variation in the abundance of immunoglobulin reads (light blue) in plasmocytes of 181 individuals. **(C)** Distribution of the proportion of variation in gene expression level accounted for by the (primary) detected *cis*-eQTL. **(D)** Results of the conditional analysis for the detection of independent secondary *cis*-eQTL effects. **(E)**  $\text{Log}(1/p\text{-value})$  of the excess number of shared modules over expectations (given number of detected eQTLs in the respective cell types) for all possible pairs of cell types. Computations are performed by including modules with two active cell types (upper left facet), three or less active cell types, four or less active cell types, ..., 27 or less active cell types (lower right facet). **(F)** Frequency distribution of the p-values obtained using an empirical cell-type x eQTL effect “interaction” test. We determined the probability to obtain a *cis*-eQTL effect that is as low or lower than the one observed in cell type B, by sampling

expression levels (bootstrapping) by variant genotype from cell type A. The large excess of low p-values is striking (uniform distribution expected on the null), yielding an estimate of  $\pi_1$  [Storey & Tibshirani, 2003] of 99.9%. **(G)** Across-gene regulatory modules grouped by the combination of cell types in which they are active and ordered by the frequency of occurrence of the corresponding pattern. Modules encompassing one gene and active in one cell type only are labeled in yellow (n = 15,926). Modules encompassing more than one gene yet active in only one cell type are labeled in red (n = 84). Modules encompassing one gene yet active in more than one cell type are labeled in blue (n = 3,433). Modules encompassing more than one gene and active in more than one cell type are labeled in green (n = 1,451). Only the 40 more common activity patterns (out of 2,959 in total) are shown. These include the 27 patterns corresponding to modules active in only one cell type. **(H)** Estimation of the proportion of gene-specific modules that merge with another gene-specific module to create a multigenic module when considering gene-specific modules active in 1, 2, 3, ... 27 cell types (x-axis). Interestingly, gene-specific modules active in one cell type rarely (11.3%) fuse with others to form multigenic modules. Likewise, gene-specific modules that are active in all 27 cell types rarely (17.1%) become multigenic modules. A contrario, gene-specific modules that are active in 2 to 26 cell type more often (average 41.4%; range: 30.1% - 53.2%) fuse with others to form multigenic modules. To make sure that the probability of merging between gene-specific modules was not affected by the number of EAPs in the modules, we exclusively used one EAP per gene-specific module, namely the consensus EAP for modules with more than one EAP.

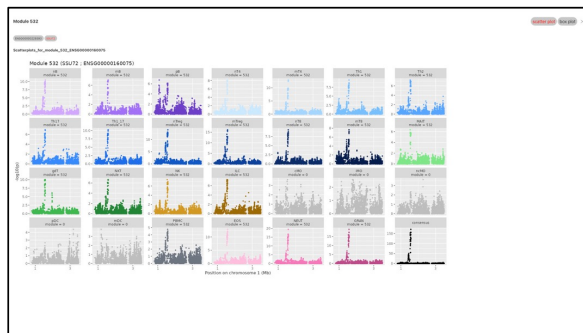

**Supplemental Figure 4: Screenshots from the CEDAR website (<https://tools.giga.uliege.be/cedar>) for the 27 circulating immune cell populations.**

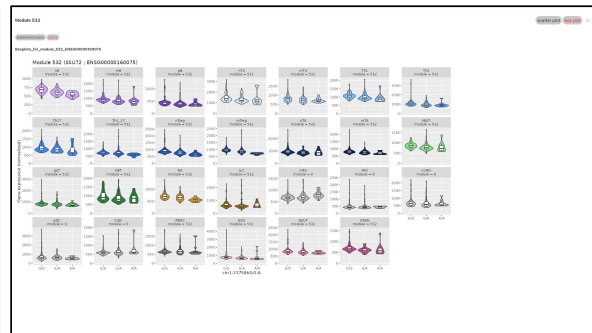

**A**

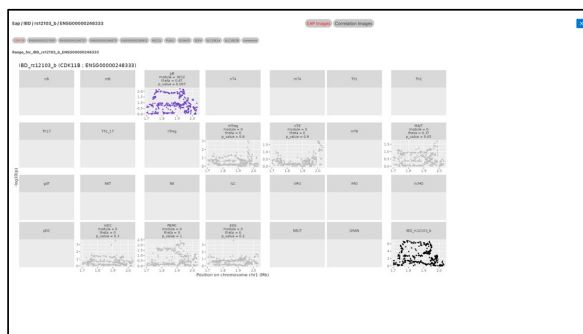

**B**

**C**

**D**

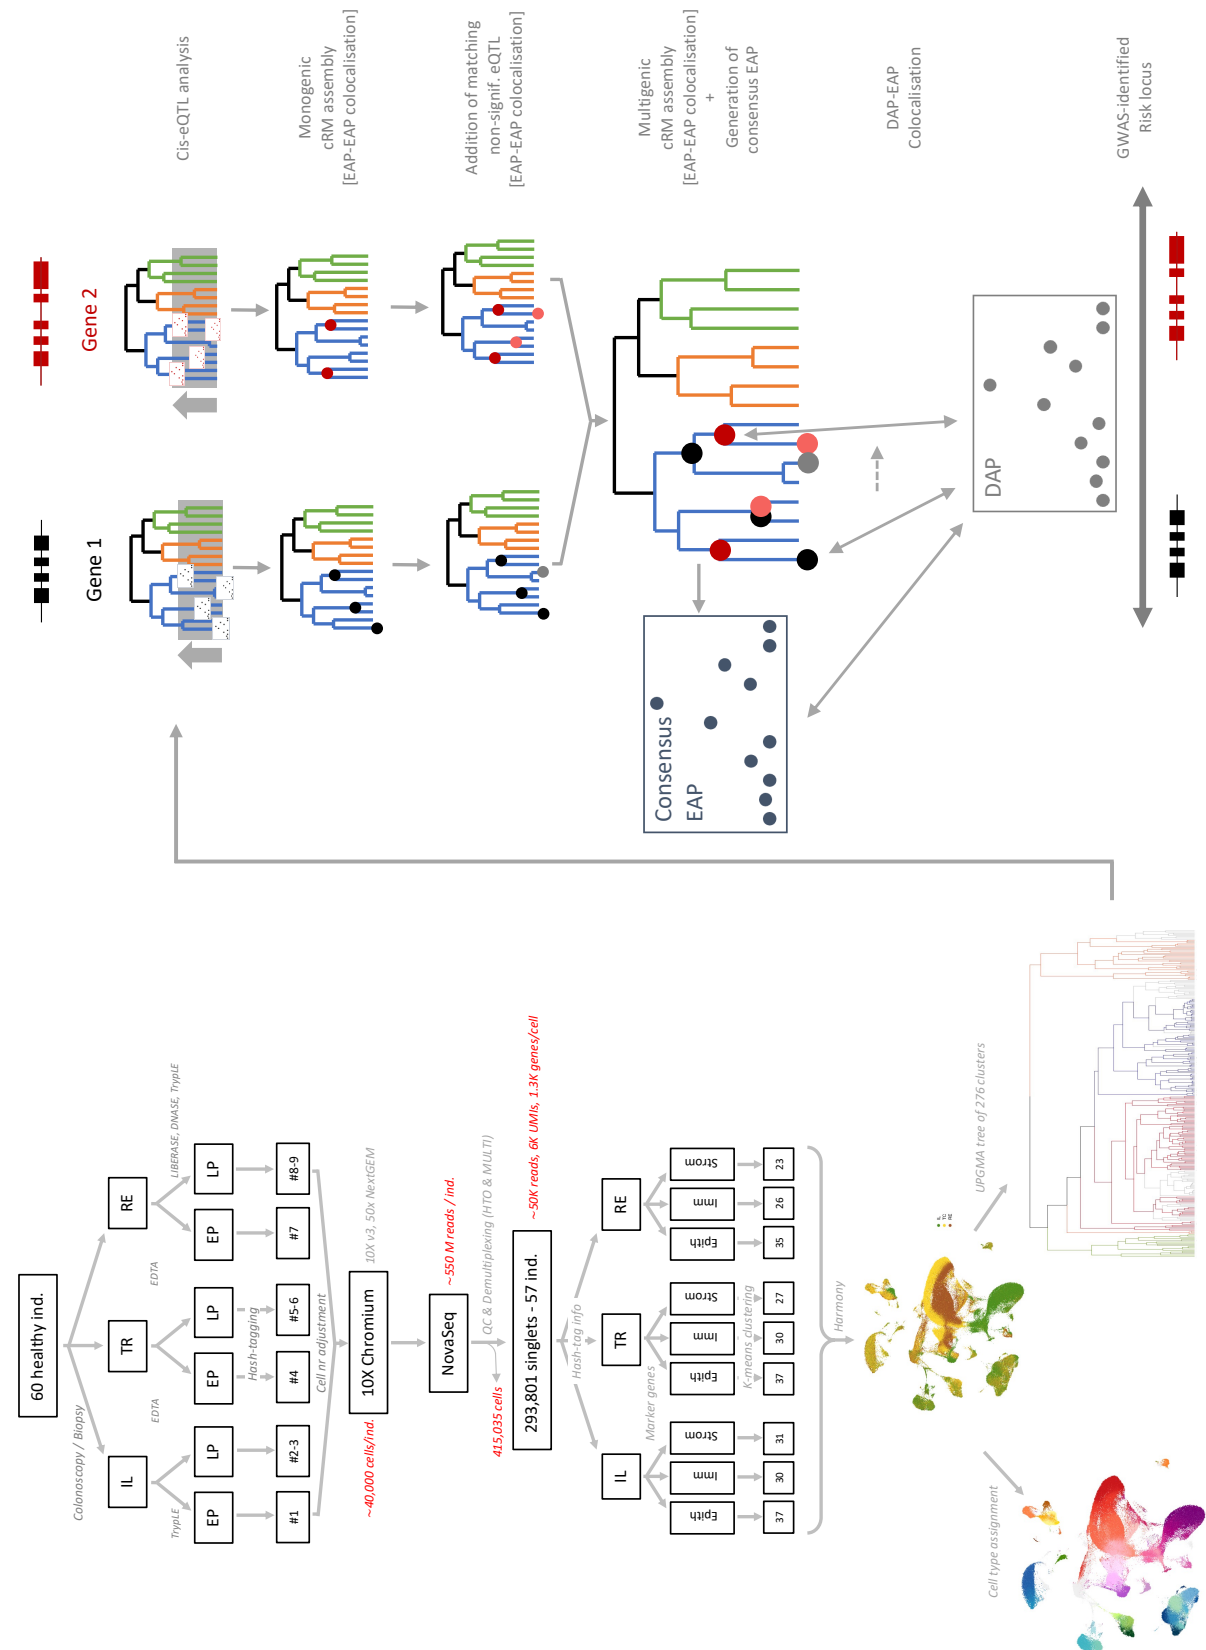

**E**

**(A)** Top panel: genome browser showing the position of genes and risk loci for inflammatory bowel disease (IBD). Bottom panel: activity of the eQTL and *cis*-acting regulatory modules (RM). Significant eQTL are marked by large arrows ( $\uparrow$ ). Arrows for eQTL that are part of the same module have the same color. eQTL in a module with effect sign opposite to the most significant eQTL in the module (“representative”) are marked by a downward pointing arrow ( $\downarrow$ ). Non-significant eQTL that are part of a module by virtue of matching EAP ( $|\theta| \geq 0.6$ ) are marked by small arrows ( $\wedge$  or  $\vee$ ). eQTL that are alone in their own module are in grey. Modules can be highlighted by clicking on them. **(B)** By clicking on a module, one has access to the EAP graphs showing the activity of the corresponding eQTL in all 27 cell types by gene (one page per gene). EAPs that are part of the selected module are colored, others are shown in grey. If the gene was not expressed in a given cell type (and

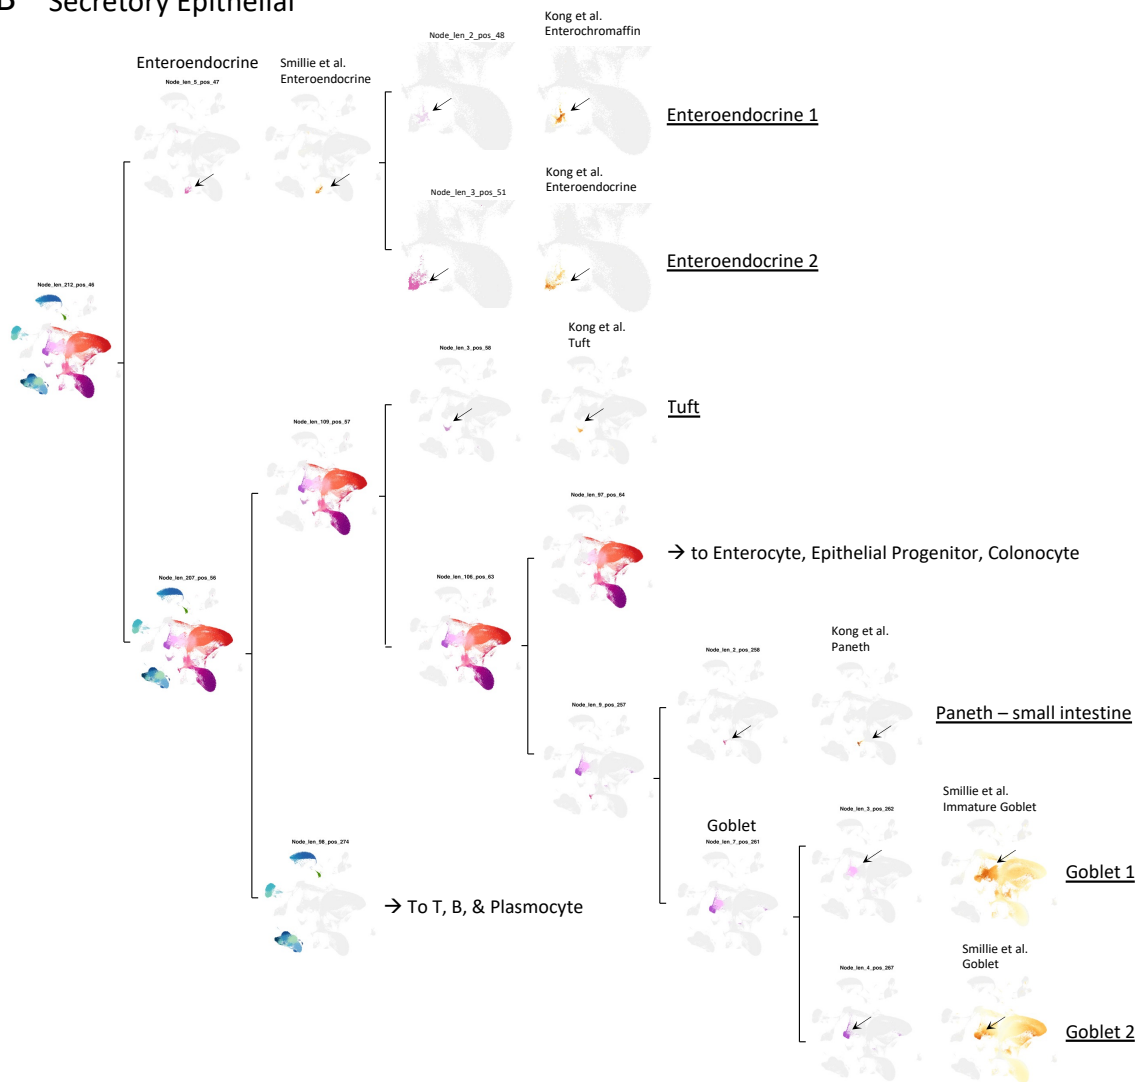

the eQTL could not be tested) the EAP graph is “empty”. The last facet (lower right) corresponds to the “consensus” EAP of the module. **(C)** By clicking on a module, one also has access to violin plots at the lead SNP of the consensus EAP showing the distribution of DESeq2 normalized gene expression values for individuals sorted by SNP genotype. **(D)** By clicking on the bars corresponding to the disease risk loci, one has access to the EAP in all 27 cell types of all genes (one page per gene) that have a matching DAP-EAP ( $|\theta| \geq 0.6$ ,  $p \leq 0.05$ ) with the corresponding DAP (lower right facet). **(E)** By clicking on the bars corresponding to the disease risk loci, one also has access to the theta-plots [Momozawa *et al.* 2018] in all 27 cell types of all genes (one page per gene) that have a matching DAP-EAP ( $|\theta| \geq 0.6$ ,  $p \leq 0.05$ ).

**(A-H)** Illustration of the cell content of the nodes and leaves of the hierarchical tree of cell clusters. The different panels sequentially walk the reader through the tree from the root towards the leaf. In terms of cellular content, each node in the tree corresponds to the agglomeration of the cells of all dependent leaves. For each node, we show the global UMAP yet color only the cells that are part of the node. The colors used correspond to the colors of Fig. 2D, with epithelial cells in reddish tones, lymphoid cells in bluish tones, myeloid cells in greenish tones, and stromal cells in orange tones. For part of the nodes, corresponding to what were, in the end, nodes identified as the upper levels of one of 49 specific cell types, we add the same UMAP yet this time labeled in pseudo-color measuring the intensity of expression of a set of signature genes. The source of the corresponding gene signature is provided, as well as the name of the corresponding cell type (underlined). If the source is one of the following references [Smillie *et al.* 2019; Hickey *et al.* 2023; Kong *et al.* 2023; Krzak *et al.* 2023], we use yellowish tones. If the source is the Azimuth human PBMC reference mapping program [Hao *et al.*, 2021], we use bluish tones. The reason why we herein mention 49 cell types as opposed to 43 in f.i. Fig. 2A, is because we herein (SFig. 6) separately highlight ileal, colonic and rectal cell clusters for some epithelial cell type, while these are considered as one in Fig. 2A. Each lower panel shows expressions of a subset of marker genes (rows) characteristic for the indicated cell types (columns) in references [Franzén *et al.* 2019; Smillie *et al.* 2019; Burclaff *et al.* 2022; Ishikawa *et al.* 2022; Hickey *et al.* 2023; Kong *et al.* 2023; Hao *et al.*, 2024].

**(I)** Seurat cell cycle phase scores, the number of RNA detected and module scores for mitochondrial genes are shown on the UMAP.

**(J)** Nodes, in the hierarchical tree, for which all dependent leaves derive from the same anatomical location (terminal ileum, transverse colon, rectum) are color-labeled accordingly. It appears that one has to go quite “high” (i.e., towards the leaves) in the tree, before colors appear. This means that for most cell types, the cells have very similar transcriptome across anatomical locations. This is especially true for myeloid and lymphoid cell types. Separation by anatomical location occurs a bit earlier in the tree for epithelial and, to a lesser extent, for stromal cells.

**Supplemental Figure 7: Screenshots from the CEDAR website (<https://tools.giga.uliege.be/cedar>) for the scRNA Seq analyses of the intestinal biopsies.**

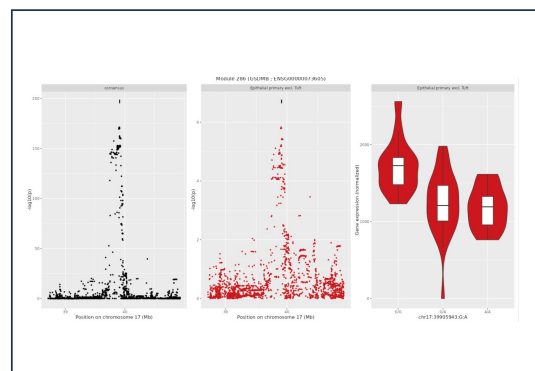

**A**

**B**

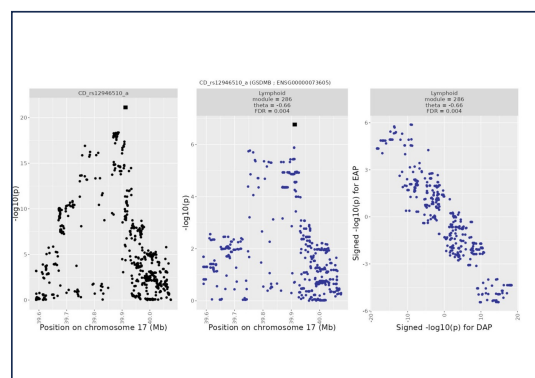

**C**

**D**

**E**

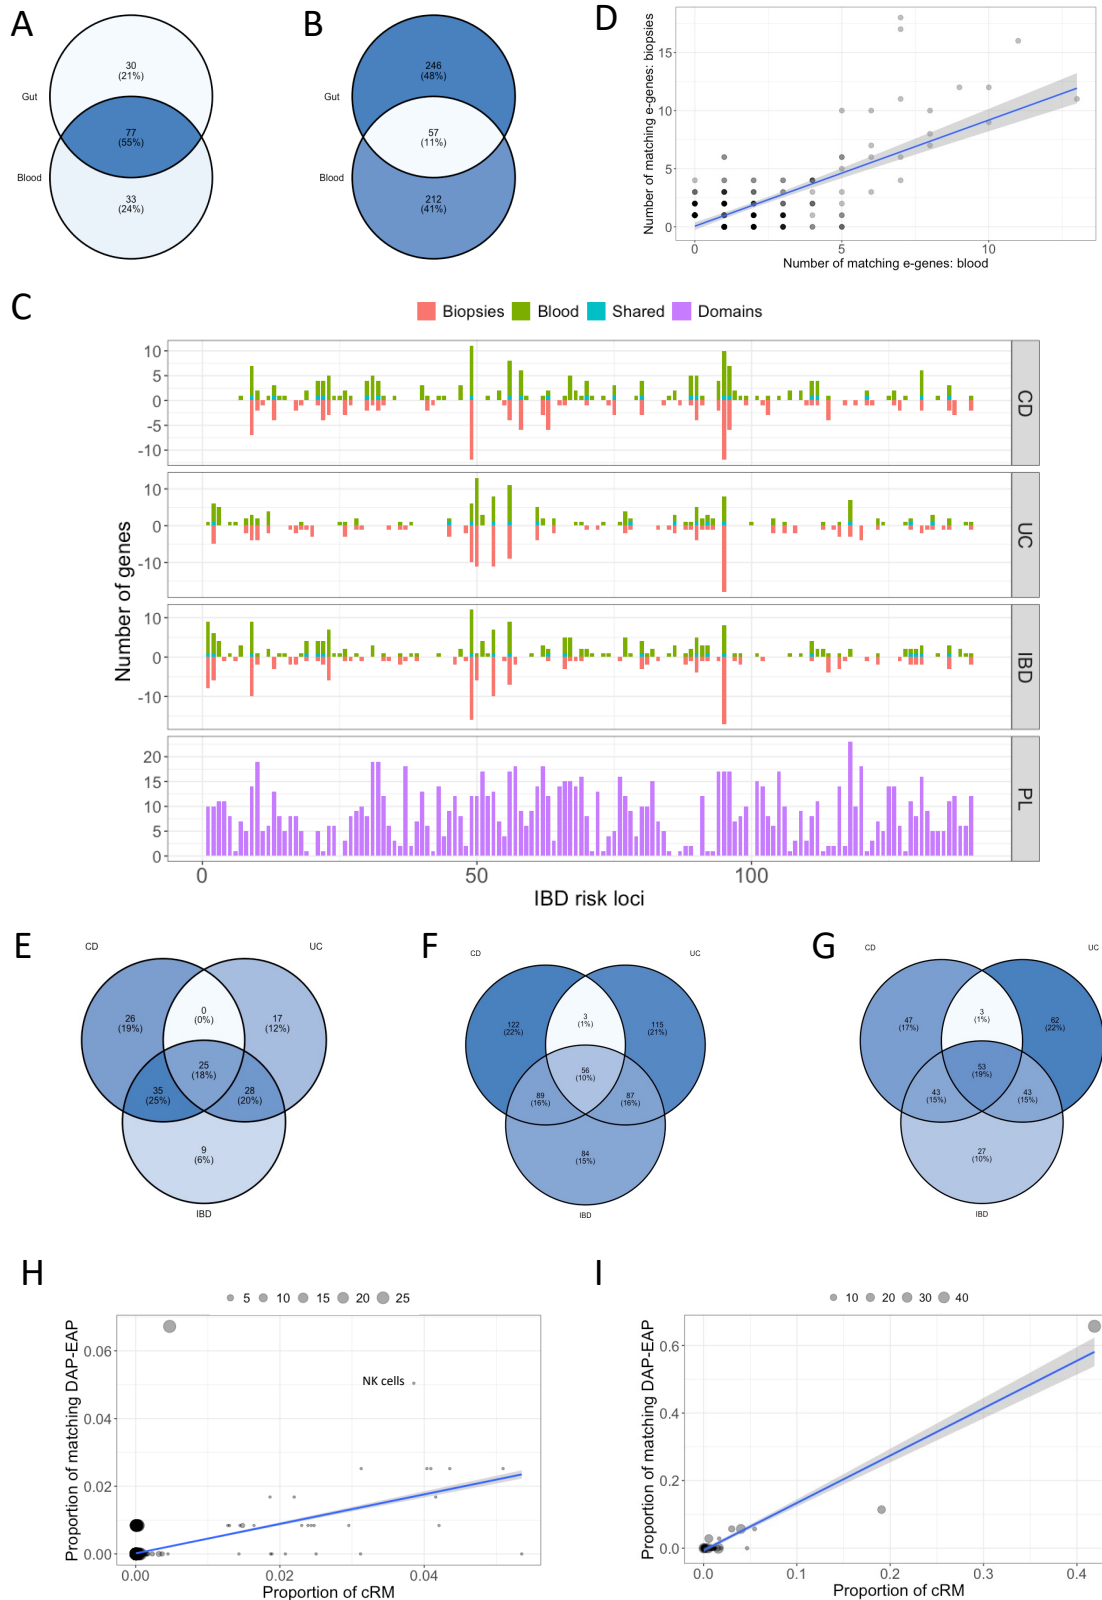

**(A)** The X axis of the main page corresponds to the genome coordinates showing, in the top panel, the position of the genes as well as the boundaries of color-coded disease risk loci (IBD, CD and UC in the example), and in the lower panel the expression levels (marbles, not shown) and eQTL activity (arrows, as in SFig. 4 for blood) for the different genes. The Y axis corresponds to the cell type hierarchy guided by the tree resulting from

hierarchical clustering of the cell clusters and their annotations to specific intestinal cell types. Clicking on a level in the cell type hierarchy shows the corresponding cell selection on the 2D UMAP. **(B)** Clicking on an arrow (corresponding to an eQTL effect) calls a set of pages for each gene in the corresponding module, each with the hierarchical tree with symbols showing the activity of the eQTL (full circles: significant eQTL, empty circles: non-significant eQTL yet matching the consensus EAP of the module). **(C)** Clicking on the symbols calls a next page that shows the consensus EAP of the module, the EAP for the selected gene for the selected position in the tree and the corresponding violin plot for the top variants of the (consensus) EAP. **(D)** Clicking on a disease locus calls a set of images corresponding to trees for all genes that show a matching EAP-DAP for the selected risk locus. **(E)** Clicking on the corresponding symbols in the image, calls gene-specific pages showing the DAP for the corresponding risk locus, the EAP for the corresponding eQTL and the theta plot.

Supplemental Figure 8:

**(A)** Number of IBD risk loci with matching DAP-EAP in intestinal biopsies only (gut, n=30), in circulating immune populations only (blood, n=33), and both in gut and blood (n=77). **(B)** Number of e-genes with matching DAP-EAP in intestinal biopsies only (gut, n=246), in circulating immune populations only (blood, n=212), and both in gut and blood (n=57). **(C)** Number of e-genes with matching DAP-EAP in 206 IBD risk loci (ordered by chromosomal position along the X-axis) in blood (green bars) and biopsies (orange bars, numbers x -1). The blue

bards correspond to the number of e-genes shared between blood and biopsies for a given risk locus. Numbers are given separately for CD, UC and IBD risk loci (see STable 21). Intestinal biopsies only (gut, n=246), in circulating immune populations only (blood, n=212), and both in gut and blood (n=57). The panel with the violet bars at the bottom, labeled “PL” (-eiotropy), reports the sum of the number of “trait domains” that are influenced by the pleiotropic genomic loci, defined by Watanabe *et al.*, 2019, that overlap with the corresponding IBD risk locus. **(D)** The number of matching e-genes (i.e., with matching DAP-EAP) in blood (X-axis) and biopsies (Y-axis) is highly correlated across the IBD risk loci, despite the fact that the corresponding e-genes mostly differ between blood and biopsies (see blue bars in panel C). **(E)** Numbers of risk loci with matching e-genes for CD, UC and IBD, with corresponding overlaps (i.e., risk loci with matching e-genes for CD and UC but not IBD (n=0), CD and IBD but not UC (n=35), UC and IBD but not CD (n=28), CD, UC and IBD (n=25)). **(F)** Numbers of matching e-genes for CD, UC and IBD, with corresponding overlaps (i.e., e-genes matching the DAP for CD and UC but not IBD (n=3), CD and IBD but not UC (n=89), UC and IBD but not CD (n=87), CD, UC and IBD (n=56)). **(G)** As for (F), yet restricting the analysis to 81 loci that are risk loci for both CD and UC. **(H)** The proportion of matching DAP-EAP involving “blood” cis-acting regulatory modules (= cRM) with a given “activity vector” (i.e., the combination of the 27 cell types in which the module is active) is correlated with the proportion of regulatory modules (= RM) with that “activity vector”. Yet, some types of modules stand out. Regulatory modules that are active in all cell types account for only 0.0047 of all across-gene modules, yet account for 0.0672 of DAP-EAP matches (> 14-fold excess), reminiscent of Momozawa *et al.* [2018]. Each dot corresponds to one of 3,572 observed activity vectors. The size of the dot corresponds to the number of “1”s in the vector (i.e., the number of cell-types out of 27 in which the module is active). The graph was obtained considering across-gene modules and the three diseases (CD, UC and IBD) combined. **(I)** The proportion of matching DAP-EAP involving “biopsy” regulatory modules encompassing a number of cell types (i.e., out of the 43 distinguished cell types; see also Fig. 2A) is correlated with the overall proportion of cognate regulatory modules (RM = cis-acting regulatory module). Yet regulatory modules assigned to the root of the hierarchical tree (Fig. 2F), and hence encompassing mostly modules that are active in many cell types, account for the highest proportion of DAP-EAP matches. Each dot corresponds to one of 64 observed cell-type groups. The size of the dot corresponds to the number of cell types (out of 43) included in the group. The graph was obtained considering gene-specific modules and the three diseases (CD, UC and IBD) combined.

### Supplemental Material 1: Comments on candidate drugs for repurposing to treat IBD with genetic support from this study.

**IL18R1 and IL18RAP.** IL18R1 and IL18RAP code for the IL18 receptor and its accessory subunit (enhancing IL18 binding), respectively. With IL1, IL18 is activated upon PAMP-recognition by the inflammasomes. Our data indicates that downregulation (predominantly) of both genes (IL18R1 and IL18RAP), primarily (but not exclusively) in circulating immune cells (including ILC, MAIT, and Th17), increases the risk to develop CD (predominantly), hence that “activating” both might have a beneficial effect. In agreement with these findings, IL18R KO mice are more susceptible to DSS-induced colitis [Takagi et al., 2003], and pre-treatment of mice with IL18 protected against DSS-induced colitis [Pu et al., 2019]. However, IL18 administration at later stages of DSS-induced colitis exacerbates symptoms [Pu et al., 2019], while administration of IL18 neutralizing antibodies reduces the severity of DSS-induced colitis [f.i. Ikegami et al., 2024]. In humans, abundance of IL18 is generally increased in IBD patients, both in blood and mucosa [Leach et al., 2008], while mendelian randomization indicates that increase in IL18 concentrations increases IBD risk [Mokry et al., 2019]. We observe an increase of IL18R1 mRNA abundance in naïve B cells of active CD patients, while Eldjarn *et al.* [2023] report an increased abundance of IL18R1 in IBD patients. Thus, the IL18 axis appears to have an anti-inflammatory effect prior to disease declaration, yet a pro-inflammatory effect after. Iboctadekin is reported as an agonist of IL18R1 and IL18RAP, and is in fact recombinant human IL18. Iboctadekin has been tested in the context of infectious diseases and oncology, but with mediocre results, and its development was discontinued. Given the apparent dual function of the IL18 axis in inflammation, the use of iboctadekin in the treatment of IBD appears difficult to support. Nevertheless, an iboctadekin-based treatment that might be considered in the context of IBD, is to prevent relapse, particularly after disease remission has been achieved following surgery, rather than its use during the active phase of the condition.

**CFTR.** Well-studied chloride channel essential for ion transport and fluid secretion in tissues, including the gastrointestinal tract, and playing an important role in mucin maturation in the intestine [Gustafsson et al., 2012]. Nullizygosity for *CFTR* causes cystic fibrosis (CF), while hemizygosity may increase resistance to infectious diseases [Bradbury, 1998]. The prevalence of IBD was shown to be 7 times higher in CF patients compared to controls [Lloyd-Still, 1994]. *A contrario*, *CFTR* hemizygosity was recently shown to protect against CD [Yu et al., 2024]. Also, glibenclamide, a (*CFTR*) inhibitor, was reported to protect rats against 2,4-dinitrobenzene sulfonic acid (DNBS)-induced gastrointestinal inflammation [Chidrawar & Alsuwayt, 2021]. In agreement with this, we herein shown that increased *CFTR* expression in intestinal epithelial and stromal cells is associated with increased risk for UC. Note, however, that there is some evidence (albeit non-significant) from our data that decreased expression of *CFTR* in specific enterocyte populations may increase CD risk, deserving further analysis in a larger dataset. Also, plasma levels of *CFTR* were found to be increased in IBD patients. This suggests that downregulating *CFTR* may improve IBD. Of note, *CFTR* has been shown to act as a pathogen recognition molecule that can induce NF- $\kappa$ B activation [Schroeder et al., 2002], and serves as epithelial receptor for *S. Typhi* transluminal migration [Pier et al., 1998]. Also, *CFTR* KO mice secreted more intestinal mucus [Norkina et al., 2004; Hodges et al., 2008], which plays a protective role in IBD. While most drug development targeting *CFTR* aims at restoring function in the context of CF, there exist at least one presumed *CFTR* inhibitor, namely crofelemer,

approved for HIV-associated diarrhea [Tradantip et al., 2010]. Crofelemer is a natural, (not so) small molecule derived from the *Croton lechleri* tree. It is taken orally to treat secretory diarrhea (as opposed to diarrhea resulting from an underlying inflammatory process) in various contexts. It has proven effective in HIV-seropositive patients on stable antiretroviral therapy [Macarthur et al., 2013]. Being primarily used for non-inflammatory diarrheal conditions, crofelemer may alleviate diarrheal symptoms IBD patients but it is unclear whether it also affects the underlying inflammatory process. Of note, inhibition of CFTR-mediated intestinal chloride secretion could be a potential therapy for bile acid diarrhea, a condition frequently present in IBD [Duan et al., 2019]. It seems important to determine whether the apparent effect of *CFTR* expression on IBD risk depends on CFTR's chloride channel activity (affected by crofelemer) or of distinct functions of this gene (such as pathogen recognition).

**LAMA2.** Codes for an  $\alpha$  subunit of laminins, an essential component of the basement membrane with important roles in tissue organization. LAMA2 deficiency causes a muscular dystrophy accompanied by an exacerbated innate immunity response, autophagy and cell death [Jeudi et al., 2011]. Intriguingly, somatic LAMA2 mutations were recurrently observed in colonic mucosa of DSS-treated mice [He et al., 2021]. LAMA2 may play a role in intestinal barrier homeostasis. Along those lines, mutations in laminins have been associated with skin blistering [Schéele et al., 2007]. We observe that variants that increase *LAMA2* expression, including in precursor and mature enterocytes, consistently increase CD risk. However, *LAMA2* expression was found to be downregulated in fibroblasts of IBD inflamed terminal ileum. Ocriplasmin is an injectable (intravitreally) protease inhibitor acting on laminins (and fibronectin) that is used to treat vitreomacular adhesion [Stalman et al., 2012; Mastrapasqua et al., 2023]. Whether it is the down- or up-regulation, or any, that is desirable in this case is uncertain. There is a need for further exploration of the link between LAMA2 and IBD, which may also involve its role in autophagy [Mastrapasqua et al., 2023].

**CYP3A5.** Codes for a member of the cytochrome P450 monooxygenases metabolizing various endo- and xenobiotics. In particular CYP3A enzymes participate in bile acid biotransformation, which – if perturbed – could contribute to the disruption of gut homeostasis in colitis patients including by affecting microbiota composition [Hayes et al., 2016; Zhang et al., 2019; Lin et al., 2020]. We observe that an increase of CYP3A5 expression in naïve CD8 increases CD risk (tier 1). However, in enterocytes of the small intestine, the opposite seems to occur (negative theta), albeit with FDR above 0.10 but potentially more relevant. There was no detectable effect of disease status on CYP3A5 expression/abundance in blood, biopsies and plasma. There exist at least two small molecule inhibitors of CYP3A5: cobicistat and ritonavir, used to boost the effectiveness of other drugs (particularly antiretroviral). Ritonavir may have independent anti-inflammatory action, as well as affect the microbiome but this appears unrelated to the observed DAP-EAP match. Genotype at CYP3A5 variants has been proposed as a guide to tacrolimus dosage in the treatment of ulcerative colitis [Okabayashi et al., 2019; Yamamoto et al., 2020], yet this bears no relationship with DAP-EAP matching.

**PTGIR.** Encodes the G protein coupled receptor of prostacyclin (PGI<sub>2</sub>). Prostacyclin is mainly known as a potent vasodilator (and inhibitor of platelet activation). Concomitantly, small molecule agonists of PTGIR (often prostacyclin mimics) are primarily used in the treatment of pulmonary arterial hypertension. However, prostaglandins, including prostacyclin, are known

to affect inflammation, having either pro-inflammatory (f.i. rheumatoid arthritis) or anti-inflammatory (f.i. allergic inflammation) effects depending on context [Stitham et al., 2011; Dorris & Peebles, 2012]. PTGIR has well-documented anti-inflammatory properties by inhibiting the production of pro-inflammatory cytokines and the immune response [Ricciotti et al., 2011]. Paradoxically, stimulating PTGIR signaling in cultured human monocytes augments calprotectin expression, a marker of inflammation [Karaky et al., 2022]. PTGIR may play a role in maintaining the intestinal epithelial barrier [Turner, 2009], and in regulating intestinal microcirculation which is impaired in IBD [f.i. Hatoum et al., 2003], and tissue repair. Of note, increased expression of the PTGER4 receptor for PGE2 (known to affect the immune system) has been associated with an increased risk for CD [Libioulle et al., 2007], yet PTGER4 knock-out mice are more susceptible to DDS-induced colitis, while PTGER4 agonists are protective [Kabashima et al., 2002]. We observe that reduced expression of PTGIR in multiple circulating T lymphocyte populations as well as resident monocytes is consistently associated with increased risk to develop UC. We don't see a clear effect of disease status on PTGIR expression/levels whether in circulating leukocytes, biopsies or plasma. We note that the use of cyclooxygenase inhibitors reportedly exacerbate symptoms in some IBD patients. As for IL18R1/IL18RAP, PTGIR activator-based treatments that could be considered in the context of IBD, are to prevent relapse, particularly after disease remission has been achieved following surgery, rather than their use during the active phase of the condition.

**INPP5D.** Encoding inositol Polyphosphate-5-Phosphatase D (=SHIP1). SHIP acts as a multifunctional protein controlled by multiple regulatory inputs, and influences downstream signaling via both phosphatase-dependent and -independent means. SHIP1 has functions in B cells, T cells, NK cells, dendritic cells, mast cells, and macrophages [Pauls & Marshall, 2017]. Downregulation is generally considered to be pro-inflammatory. SHIP deficiency causes Crohn's disease-like ileitis in the mouse [Kerr et al., 2011], while deficiency in Inflammatory Bowel Disease is associated with severe Crohn's disease and peripheral T cell reduction [Fernandes et al., 2018]. Accordingly, we observe that *INPP5D* downregulation in circulating T lymphocytes, MAIT and NK cells, as well as resident monocytes increases CD risk. Also, *INPP5D* expression is decreased in circulating monocytes from IBD patients. The small molecule rosiptor, the most developed and characterized allosteric activator of *INPP5D*, has been unsuccessfully tested as anti-inflammatory drug to treat interstitial cystitis and bladder pain syndrome and its development has been discontinued [<https://www.pharmaceutical-technology.com/news/aquinox-halts-development-drug-bladder-pain-syndrome/>]. Binding of rosiptor to SHIP1 was shown to be weak when compared to other agonists which may in part explain poor clinical results [Chamberlain et al., 2020; Pedicone et al., 2021]. We conclude that rosiptor is probably not an optimal candidate for repurposing.

**NEK7.** NIMA Related Kinase 7, plays a central role in assembly of the NLRP3 inflammasome [Shi et al., 2016]. Missense *NLRP3* mutation cause dominant congenital multisystem inflammatory diseases (Cinca (MIM 607115) and Muckle-Wells syndromes (MIM 191900)). Downregulating *NEK7* by intraperitoneal injection of lentiviruses expression anti-*NEK7* shRNAs attenuates DSS-induced colitis [Chen et al., 2019]. We observe that variants that increase *NEK7* expression in circulating naïve B cells increase CD risk. Of note, however, these same variants appear to decrease *NEK7* expression in gut-resident lymphoid and myeloid immune cells, albeit with FDR > 0.10, hence inverting the association with CD (decreased expression increases risk). Disease affects *NEK7* expression but the sign of the affect depends

on cell type: expression is increased in enterocytes from non-inflamed colon of patients when compared to controls, while expression is increased in some and decreased in other circulating immune cells of patients. Entrectinib (ENB) is a potent tyrosine multikinase small-molecule inhibitor that targets the NTRK, ROS1 and ALK oncogenes, approved by the FDA for the treatment of various tumors [Liu et al., 2018]. It was recently shown to bind to NEK7 R121, and interferes with its interaction with NLRP3. In mouse models, ENB effectively reduced symptoms of NLRP3 inflammasome-related diseases (other than colitis), indicating its potential as a therapeutic candidate [Jin et al., 2023]. ENB has a high safety profile and is well tolerated by almost all patients without cumulative toxicity [Jiang et al., 2022]. Inhibition of the inflammasome has shown beneficial effects in various inflammatory pathologies. ENB appears may be a repurposing candidate for IBD.
