Short title: EchoNet-LVH Validation

Word count: [follow target journal guidance]

ABSTRACT

Background

Diagnosis of cardiac amyloidosis (CA) is often missed or delayed due to confusion with other causes of increased left ventricular wall thickness. Conventional transthoracic echocardiographic measurements like global longitudinal strain (GLS) has shown promise in distinguishing CA, but with limited specificity. We conducted a study to investigate the performance of a computer vision detection algorithm in across multiple international sites.

Methods

EchoNet-LVH is a computer vision deep learning algorithm for the detection of cardiac amyloidosis based on parasternal long axis and apical-4-chamber view videos. We conducted a multi-site retrospective case-control study evaluating EchoNet-LVH's ability to distinguish between the echocardiogram studies of CA patients and controls. We reported discrimination performance with area under the receiver operating characteristic curve (AUC) and associated sensitivity, specificity, and positive predictive value at the pre-specified threshold.

Results

EchoNet-LVH had an AUC of 0.896 (95% CI 0.875 – 0.916). At pre-specified model threshold, EchoNet-LVH had a sensitivity of 0.644 (95% CI 0.601 – 0.685), specificity of 0.988 (0.978 – 0.994), positive predictive value of 0.968 (95% CI 0.944 – 0.984), and negative predictive value of 0.828 (95% CI 0.804 – 0.850). There was minimal heterogeneity in performance by site, race, sex, age, BMI, CA subtype, or ultrasound manufacturer.

Conclusion

EchoNet-LVH can assist with earlier and accurate diagnosis of CA. As CA is a rare disease, EchoNet-LVH is highly specific in order to maximize positive predictive value. Further work will assess whether early diagnosis results in earlier initiation of treatment in this underserved population.

INTRODUCTION

Cardiac amyloidosis (CA) is caused by deposition of misfolded proteins in the myocardium, including transthyretin (ATTR) or immunoglobulin light chains (AL). Regardless of the etiology, CA leads to increased left ventricular wall thickness and heart failure, however early symptoms can be non-specific and not readily recognized. Common echocardiographic measurements are insufficient to precisely discriminate CA from other etiologies of left ventricular hypertrophy (LVH) or heart failure.

There is concern that CA is underdiagnosed and diagnosed too late[3-5], which limit the opportunity to receive recent targeted therapies that improve quality of life and decrease mortality outcomes in CA patients[6,7]. Recent research has focused on methods that can assist with early identification of CA. Echocardiography is one of the most common initial tests when evaluating patients with heart failure symptoms, with typical CA features on including increased left ventricular wall thickness, normal or small left ventricular cavity, preserved left ventricular ejection fraction (LVEF), and diastolic dysfunction[10]. However, many of these features are also commonly found in other forms of heart failure with preserved ejection fraction[11,13]. Individually, these measurements have limiting ability to specifically identify CA, resulting in imaging cardiologists to hesitate to highlight suspicion for CA.

Recent advances in computer vision and artificial intelligence (AI) have enabled precision
phenotyping of structure and function in cardiac ultrasound. AI applied to echocardiography can
precisely estimate wall thickness[20], assess mitral regurgitation severity, and left ventricular
ejection fraction (LVEF) as well as detect cardiac amyloidosis, HCM, and diastolic dysfunction. However, many algorithms have not been rigorously validated in multiple centers or undergone prospective evaluation of performance. As such, significant work is needed to evaluate the true performance at individual sites.

In this study, we evaluated the performance EchoNet-LVH, a previously developed a computer vision deep learning algorithm for the detection of cardiac amyloidosis, across multiple new healthcare systems and videos that the model has never seen before. We conducted a multi-site international retrospective case-control study evaluating EchoNet-LVH's ability to distinguish between the echocardiogram studies of CA patients and controls. We reported discrimination performance with area under the receiver operating characteristic curve (AUC) and associated sensitivity, specificity, and positive predictive value at a pre-specified threshold to raise suspicion for CA.

METHODS

Study Design

We conducted an international multicenter retrospective case-control cohort study with participants from multiple geographically distinct healthcare systems to evaluate EchoNet-LVH. EchoNet-LVH was previously developed using CA cases and controls from Stanford Healthcare[20], so this study serves as temporally and geographically distinct external validation. Patients were sourced from Cedars-Sinai Medical Center in Los Angeles, California, Keio University in Tokyo, Japan, Northwestern Medicine in Chicago, Illinois, and Yale-New Haven Hospital in New Haven, Connecticut. A total of 520 patients were identified as having CA and matched to 903 randomly selected controls from patients receiving echocardiography and at least 65 years of age. CA patients were were diagnosed with transthyretin (ATTR), light chain (AL) amyloidosis, or other forms of cardiac amyloidosis using a combination of pyrophosphate scintigraphy, monoclonal gammopathy testing, genetic testing, and/or tissue biopsy. The controls either had negative testing for cardiac amyloidosis or testing was not performed. Given the low population prevalence of CA, the likelihood of undiagnosed CA in the controls was thought to be minor and unlikely to change the anlaysis. This study was approved by the Cedars-Sinai Institutional Review Board.

Computer Vision Model

EchoNet-LVH's development approach and internal validation has been previously described[20]. In short, EchoNet-LVH is an automated machine learning pipeline that automatically identifies parasternal long axis and apical-4-chamber views from transthoracic echocardiogram studies, precisely measures wall thickness, and assesses texture and motion from the apical-4-chamber view echocardiogram videos to assess suspicion for cardiac amyloidosis. Information from the apical-4-chamber view is synthesized with a segmentation model's assessment of wall thickness from the parasternal long axis videos to come up with a suspicion for CA. Given the low population prevalence of CA, a prespecified threshold (0.8) in the summative assessment was chosen to optimize and prioritize for specificity, which in turn, maximizes positive predictive value. Echocardiogram videos were obtained in DICOM format and a fully automatic pipeline analyses the study.

Statistical Analysis

Continuous variables were reported using median (interquartile range), and categorical variables were reported with number (percentage). Performance of TTE measurements, GLS measurements, and ratios in discriminating CA was evaluated using area under the receiver operator curve (AUC). Ninety-five percent confidence intervals were assessed for all analyses. Statistical analysis was performed in Python (Python Software Foundation, Beaverton, Oregon).

RESULTS

Demographics and clinical characteristics of the study cohort are shown in **Table 1**. The mean age of the cohort was 78.2 (IQR 72 – 84) and 77.7% male. In the cases, there was representation from both AL (22.7%) and ATTR (74.2%) amyloidosis. There was a wide range of age, BMI, and ultrasound manufacturers across the sites.

EchoNet-LVH had an overall AUC of 0.896 (95% CI 0.875 - 0.916) with minimal site level variation in performance (**Table 2**). The lowest site AUC was YNHH with an AUC 0.860 (95% CI 0.818 – 0.898) and the highest site AUC was Keio University with an AUC of 0.944 (95% CI 0.911 – 0.971). The overall sensitivity was 0.644 (95% CI 0.601 – 0.685) and the overall specificity was 0.988 (95% CI 0.978 – 0.994). There was no significant heterogeneity in other performance characteristics across site. At a 2:1 ratio of controls to cases, EchoNet-LVH had a PPV of 0.968 (95% CI 0.944 – 0.984) and a NPV of 0.828 (95% CI 0.804 – 0.850).

EchoNet-LVH also had similar performance across patient characteristics and ultrasound manufacturer (**Table 3**). EchoNet-LVH had an AUC of 0.921 (95% CI 0.882 - 0.955) for detecting AL cardiac amyloidosis and an AUC of 0.887 (95% CI 0.862 - 0.911) for detecting ATTR cardiac amyloidosis. Our model had similar performance for men (AUC of 0.893 [95% CI 0.869 – 0.914]) and women (AUC of 0.904 [95% CI 0.849 – 0.950]). There was no significant heterogeneity by race, age, BMI, or ultrasound manufacturer. Across all key groups, there was similar sensitivity and specificity of our approach, and there was no trend for differences in performance across subclasses.

DISCUSSION

In this study, we evaluated the performance of a computer vision driven AI workflow for the detection and screening of cardiac amyloidosis across a wide range of patients from an international cohort of geographically distinct healthcare systems. In this setting, we found EchoNet-LVH had strong performance in identifying patients with CA of all subtypes, and its performance was consistent across sites, ultrasound manufacturers, and patient characteristics.

A few things are worth considering in evaluating our algorithm. Because increased wall thickness is a hallmark of CA[22], our algorithm automated the approach to precisely measuring wall thickness as well as integrated this precise measurement with more 'black box' features of motion and texture assessed in the apical-4-chamber view. Our approach homes to minimize or exclude confounders[23], as our models were trained on controls matched on wall-thickness and limit the potential of AI models to shortcut on wall thickness alone. Second, our approach sought to maximize positive predictive value in the downstream testing of CA[24]. In a rare disease, PPV is significantly impacted by model specificity (as the number of false positives are likely to outweigh the number of potential true positives). We sought to find a balance of sensitivity and specificity as to minimize the number of false positives rejected in downstream testing.

A few limitations are worth considering as further study is still warranted. Prospective trialing of CA screening approaches has not yet completed. There is less data on the true population prevalence of CA, which significantly impacts the PPV of any algorithm. Multiple other measurements and approaches have been suggested to screen for CA[16], however our results is one of the few fully automated pipelines. Additionally, other work has assessed the performance of EchoNet-LVH in comparison to score-based decision aids and EHR-based algorithms and show EchoNet-LVH's superior performance[36]. Furthermore, there is significant observer variability in most echocardiographic measurements[33], which limit the precision of approaches based on routine echo measurements alone[18].

In this study comparing CA patients with patients who were referred for pyrophosphate scintigraphy but had CA ruled out, we demonstrate that IVSd/GLS can be used to identify CA in a population with high clinical suspicion for CA. This ratio has superior performance compared to individual echocardiographic measurements as well as other ratios that are already abnormal in patients at high suspicion for CA. If validated in future studies, incorporation of this easily obtainable measurement can assist with earlier diagnosis of CA resulting in reduced morbidity and mortality.

Disclosures
